Second, another important trend is the rapid pace of technological innovations in telecommunications. New developments will create more future opportunities. For example, advances with media-rich technologies enable communication that narrows the gap between virtual and face-to-face interactions. However, there is little understanding about the relationship between technological adoption and team members from different cultural backgrounds. Given cultural differences, an important consideration would be how people will relate to technological innovations. This has implications for how leaders will manage GVTs. This research issue also has implications for firms engaged in developing CMCSs, because it will affect market adoption.

Last, although not least, organizations also will need to keep pace with the growth of GVTs by developing supporting policies, compensation schemes, and investments. GVT leaders can make important contributions to facilitate organizational development and change management.

The existing GVT literature has some preliminary theoretical developments that require rigorous empirical research. Future research needs to draw from intercultural management,

organization development (OD), and CMCSs with interdisciplinary research teams. OD researchers and practitioners will provide an important contribution to different levels of change—individual, groups and teams, organizational, and interorganizational—as managers and organizations engage in change processes to incorporate GVTs for future strategic tasks.

CONCLUSION

The use of global virtual teams is a relatively new organizational design. GVTs allow organizations to span time, space, and organizational and national boundaries. But many organizational GVT practices have a trial and error approach that entails high costs and falls short of fulfilling expectations. The cost of establishing GVTs and their lackluster performance creates a demand for researchers to figure out how to resolve a range of complex issues. An important starting point is with the leadership for managing GVTs. Developing a balanced portfolio of five major leadership competencies—CMCS proficiency, work process and team designs, cross-cultural competence, interpersonal communication, and self-management—increases the likelihood of achieving high performance by GVTs.

KEY TERMS

Asynchronous Communication: Information exchanges sent and received at different times, often taking place in geographically dispersed locations and time zones.

CMCS: Computer-mediated communication system includes a wide range of telecommunication equipment such as phones, intranets, Internets, e-mail, group support systems, automated workflow, electronic voting, audio/video/data/desktop video conferencing systems, bulletin boards, electronic whiteboards, wireless technologies, and so forth to connect, support, and facilitate work processes among team members.

Colocation: Team members sharing the same physical location, which allows for face-to-face interaction.

Emotional Intelligence: A set of competencies that derive from a neural circuitry emanating in the limbic system. Personal competencies related

to outstanding leadership include self-awareness, self-confidence, self-management, adaptability, emotional self-control, initiative, achievement orientation, trustworthiness, and optimism. Social competencies include social awareness, empathy, service orientation, and organizational awareness. Relationship management competencies include inspirational leadership, development of others, change catalyst, conflict management, influence, teamwork, and collaboration.

Human Capital: The knowledge, skills, abilities, and experiences of employees that provide value-added contributions for a competitive advantage in organizations.

Netiquette: This is a combination of the words "etiquette" and "Internet" ("net," for short). Netiquette is rules of courtesy expected in virtual communications to support constructive interpersonal relationships in a virtual environment.

Synchronous Communication: Information exchanges taking place in the same space and time, often face-to-face.

Temporal Coordination Mechanism: A process structure imposed to intervene and direct the pattern, timing, and content of communication in a group.

Chapter 6.3
Short Message Service (SMS) as an Advertising Medium

Shintaro Okazaki
Autonomous University of Madrid, Spain

INTRODUCTION

The proliferation of the Internet-enabled mobile device has extended into many parts of the world. Collectively, the mobile-network operators paid more than $100 billion for licenses to operate "third-generation" (3G) networks, which were among "the largest bet in business history on the introduction of a new technology" (Economist, 2005). This drastic move has been most illustrated by the use of short message service (SMS) and multimedia messaging service (MMS) by mobile users. For example, a recent survey indicates that SMS in the Asia-Pacific region will increase to up to 75% of mobile subscribers in 2006 (IDC Asia/Pacific, 2003). As a result, marketers and agencies are increasingly interested in taking advantage of this growth, by incorporating SMS advertising as part of an integrated marketing communications (IMC) strategy. However, there has been little academic research on mobile advertising, perhaps because its growth is still in an early stage and the technological infrastructure varies across markets. The study has two objectives: (1) to identify the factors influencing MNCs' managerial intention to adopt SMS advertising, and (2) to test a statistical relationship between these factors and managerial intention to use SMS advertising. To this end, we conducted telephone interviews of senior executives of MNCs operating in European markets.

CONCEPTUAL FRAMEWORK AND HYPOTHESES

Branding Technique

In an environment where building the brand is a fundamental goal for many managers, the need to build brand equity is likely to be at the center of many marketing decisions. Firms using SMS-based campaigns can attract consumer attention and produce consumer responses to a much greater degree than via other direct marketing channels, because SMS has been claimed to be an effective tool in building and testing customer loyalty by developing demographic databases (Mylonopoulos & Doukidis, 2003). From an industry perspective, McDonald's conducted a

text-messaging campaign in conjunction with a popular TV song contest in the UK, offering concert tickets and backstage passes, while entry in the Coca-Cola Grand Sweepstakes Competition was offered to U.S. college students who sent a text message to a number printed on a Diet Coke can (Dano, 2002).

Facilitating Conditions

Lu, Yu, Liu, and Yao (2003) suggest that facilitating conditions are one of the most important determinants, along with the ease of using wireless Internet. In this light, the integration of competing standards and fragmented systems across countries, cross-network support for SMS, and higher connection speeds are all necessary conditions for a wider transmission of mobile advertising. In addition, the availability of Web-enabled mobile handsets with 2.5G or 3G functionality would significantly affect the adoption of MMS-based (multimedia message services) campaigns. In this light, a wider selection of handsets must be available, to enable consumers to choose their preferred combination of necessary functions and diverse features.

Location-Based Services

The satellite-based global positioning system (GPS) offers the ability to tailor services and promotional offers to individual consumers' needs, by locating their position (Sadeh, 2002). Mobile handset makers and content providers are increasingly attracted by the commercial feasibility of applying GPS to their service. For example, on an extended menu of i-mode, "i-area" includes a diverse range of location-based services: weather news, restaurant guide, local hotel information, zoomable maps with an address finder function, and traffic updates and estimation of travel times. This facility would give MNCs strategic leverage in mobile marketing, because individuals' behavior and receptiveness to advertising is likely to be influenced by their location and time, and marketers can thus induce impulse buying by providing the right information for the right place (Barnes, 2002).

Connection Costs

Another important factor is the concept of connection costs. For example, to send or receive one megabyte of data on 2.5G i-mode costs 32 euros (0.3 yen) per packet. At a rate of 19 euro cents per 160-character SMS message, European consumers would have to pay 1,356.98 euros to send one megabyte of data by SMS, or approximately 62 times as much as the Japanese pay (Scuka, 2003). In addition, European mobile operators have passed on to consumers the additional costs incurred in obtaining 3G spectrum licenses, and this has made any dramatic price reduction impossible (Baldi & Thaung, 2002). Such cost factors adversely affect mobile players' revenues.

Public Regulation

The idea behind mobile *advertising* is very similar to e-mail on the wired Internet, but with one big difference: it is "opt-in." This function is essential to give users total control over what they receive, because consumers' demand for highly personalized messages has to be reconciled with their desire for privacy (Sadeh, 2002). The Mobile Marketing Association (MMA) has attempted to establish industry guidelines for mobile marketers, as follows: (1) MMA members should not send mobile advertising without confirmed opt-in, and (2) such opt-in subscriber permission is not transferable to third parties without explicit permission from the subscriber (Petty, 2003).

Lifestyle and Habits

In general, European consumers habitually commute by car, and this provides fewer incentives to access the mobile Internet (Baldi & Thaung,

2002). In addition, a systematic "word-of-mouth" helped the rapid diffusion of i-mode in Japan, especially given the "normative beliefs attributed to significant others (friends, colleagues, or family members) with respect to adopting or continuing to use the technology" (Barnes & Huff, 2003). This may partially explain a high subscription rate (almost 75%) to e-mail newsletters among i-mode users, and this makes acceptance of mobile advertising much easier. However, this factor is unlikely to be present in many European countries, which are characterized as more individualist than Asian countries.

On the basis of the preceding discussions, the following hypotheses were formulated to test the principal thesis of the research:

- **H1:** MNCs' intention to adopt SMS-based advertising is directly and positively associated with branding technique.
- **H2:** MNCs' intention to adopt SMS-based advertising is directly and positively associated with facilitating conditions.
- **H3:** MNCs' intention to adopt SMS-based advertising is directly and positively associated with location-based services.
- **H4:** MNCs' intention to adopt SMS-based advertising is directly and negatively associated with connection costs.
- **H5:** MNCs' intention to adopt SMS-based advertising is directly and negatively associated with public regulation.
- **H6:** MNCs' intention to adopt SMS-based advertising is directly and negatively associated with lifestyle and habits.

METHODOLOGY

Questionnaire Items and Measures

A structured questionnaire was prepared, drawing on prior literature. A majority of the items were originally developed for this study, because of the scarcity of empirical research on mobile advertising. Each item was measured on a Likert-type five-point scale. A five-point scale was preferred to a seven-point scale, because telephone interviews were used, rather than a mail or other form of paper-and-pencil survey. This method was considered more appropriate because mobile advertising is still in its infancy, and company executives may not be able to make fine distinctions regarding their attitudes on this topic. During the telephone interview, interviewers followed a script. However, respondents were free to ask questions whenever they encountered definitional problems.

Table 1. Regression analysis and hypotheses testing

Hypotheses	Independent Variables		Standardized β		Results
H1	Branding technique		.553	**	Supported
H2	Facilitating conditions		.325	**	Supported
H3	Location-based services		.023		Rejected
H4	Connection costs		-.397	**	Supported
H5	Public regulation		.125		Rejected
H6	Lifestyle and habits		-.115		Rejected
		R^2	.598	**	
		ΔR^2	.013		
		ΔF	1.509		

Multinational Corporations

With regard to Japanese firms, the selection was based on the *Multinational Companies Database*. The database was created by the Research Institute for Economics and Business Administration at Kobe University (2003) and includes Japanese companies listed in the first section of the Tokyo Stock Exchange with foreign direct investment in more than five countries (Kobe University, 2003). American firms were chosen from The Forbes 500 (*Forbes*, 2003a). Finally, European firms were singled out from The Forbes International 500 (*Forbes*, 2003b), because this list indicates the nationality of each firm. Regardless of nationality, however, companies associated with aerospace and defense, food and drug retail chains, forestry and fishery, general public utilities, health care providers, heavy machines, industrial goods, local banking and insurance, metals and mining, and oil and gas extraction were excluded. Next, firms operating in Spain were identified. As a result, 43 Japanese, 47 American, and 31 European firms' Spanish subsidiaries were identified.

Telephone Interview

Telephone interviewing was considered appropriate because of the novelty of the research subject. It was expected that interviewers would be able to clarify doubts or answer any questions that interviewees might have regarding mobile communications. To this end, four bilingual assistants were employed (two Spanish and two Japanese, all fluent in English). During the second and third weeks of February 2004, intensive training was provided so that the assistants could gain sufficient skills and knowledge to conduct the telephone interview. The actual interviewing was carried out during March 2004, under the supervision of the researcher. It was established that when the target executives were absent or unavailable for interview, assistants had to ask: (1) for an appointment for the next phone call, or (2) about the availability of the person next in seniority in the marketing department to the target executive. As a result, a total of 53 interviews was conducted, with 27, 16, and 10 respondents from Japanese, American, and European firms, respectively. The response rate was 43.8%.

FINDINGS

First, an exploratory factor analysis with Equamax rotation with Kaiser Normalization was carried out. The rotation, converged in 12 iterations, produced a clear-cut six-factor solution with a cut-off value of .50. Only factors with eigenvalue greater than 1 were retained. It should be noted that the proposed construct "connection costs" was merged into a mixed construct "security and costs." However, because of the exploratory nature of the study, it was considered acceptable to use this six-factor solution for the subsequent analysis. The extracted factors explain 68.6% of the total variance, and the level of loading is consistently high across the six factors. Factor scores were retained as variables with the Anderson-Rubin method to minimize the level of multicollinearity, for the use of regression analysis. The reliability was calculated with Chronbach's alpha for each construct. The scores range from .60 to .85, exceeding the cut-off point of .60 suggested by Hair, Anderson, Tatham, and Black (1998). Next, the hypotheses were tested by performing regression analysis with a step-wise method. Each of six independent variables (i.e., factor scores) was regressed on the dependent variable, "MNCs' intention to use mobile advertising," in order of their expected contributions. The results of regression analysis are shown in Table 1.

DISCUSSION

This study aims to identify MNCs' principal perceptions of SMS-based push-type mobile

advertising and their intention to use it. On the basis of the data obtained from 53 MNCs, our principal propositions were tested by multiple regression analysis. The results were mixed: only half of the six hypotheses gained empirical support. The regression analysis identified branding technique, facilitating conditions, and connection costs as the three primary predictors influencing MNCs' intention to use mobile advertising. The contribution of branding technique in particular is substantial, indicating that MNCs are likely to perceive mobile advertising as an effective branding tool to increase brand awareness and image. Also, technological infrastructure and the availability of sophisticated mobile handsets are prerequisites for mobile marketing. As expected, unfavorable mobile Internet pricing negatively affects the MNCs' intention to use mobile advertising. On the other hand, the contributions of location-based services, public regulation, and lifestyle and habits are not only statistically insignificant, but also trivial in terms of the coefficient magnitude. One reason why location-based services were not identified as a significant factor is that the GPS system is not as widespread in Europe as it is in Japan. In addition, many Scandinavian firms, leaders of sophisticated mobile Internet service practitioners, were not included in the study. Admitting the danger of simple generalization, the findings of this study may imply that MNCs are concerned to a lesser extent with regulatory and cultural impediments to adopting mobile advertising.

KEY TERMS

Barcode Mobile Coupon: Mobile barcoding can be used in the form of a picture SMS which is delivered to a mobile phone. Recipients save the image, arrive at the destination, and present their barcode SMS to be scanned.

i-Mode: A broad range of Internet services for a monthly fee of approximately three euro, including e-mail, transaction services (e.g., banking, trading, shopping, ticket reservations, etc.), infotainment services (e.g., news, weather, sports, games, music download, karaoke, etc.), and directory services (e.g., telephone directory, restaurant guide, city information, etc.), which offers more than 3,000 official sites accessible through the i-mode menu.

Push Messaging Service: Various forms of messaging services are generally offered in mobile Internet. For example, SMS and WAP Push messaging generally allow users to send 100-160 characters, while mobile e-mail in Japanese i-mode allows up to 1,000 characters.

SPAM: Unsolicited or undesired bulk electronic messages. Because of the development of anti-SPAM programs, they are often deleted without being opened.

SPIM: A variation of SPAM through instant messaging systems.

Chapter 6.4
V-Card:
Mobile Multimedia for Mobile Marketing

Holger Nösekabel
University of Passau, Germany

Wolfgang Röckelein
EMPRISE Consulting Düseldorf, Germany

ABSTRACT

This chapter presents the use of mobile multimedia for marketing purposes. Using V-Card, a service to create personalized multimedia messages, as an example, the advantages of sponsored messaging are illustrated. Benefits of employing multimedia technologies, such as mobile video streaming, include an increased perceived value of the message and the opportunity for companies to enhance their product presentation. Topics of discussion include related projects, as marketing campaigns utilizing SMS and MMS are becoming more popular, the technical infrastructure of the V-card system, and an outline of social and legal issues emerging from mobile marketing. As V-card has already been evaluated in a field test, these results can be implemented to outline future research and development aspects for this area.

INTRODUCTION

The chapter presents the use of mobile multimedia for marketing purposes, specifically focusing on the implementation of streaming technologies. Using V-card, a service for creating personalized multimedia messages, as an example, the advantages of sponsored messaging are illustrated. Topics of discussion include related projects, as marketing campaigns utilizing SMS and MMS are becoming more popular, the technical infrastructure of the V-card system, and an outline of social and legal issues emerging from mobile marketing. As V-card has already been evaluated in a field test, these results can be implemented to outline future research and development aspects for this area.

Euphoria regarding the introduction of the universal mobile telephony system (UMTS) has evaporated. Expectations about new UMTS services are rather low. A “killer application” for 3rd generation networks is not in sight. Users are primarily interested in entertainment and news, but only few of them are actually willing to spend money on mobile services beyond telephony. However, for marketing campaigns the ability to address specific users with multimedia content holds an interesting perspective.

Advertisement-driven sponsoring models will spread in this area, as they provide benefits

to consumers, network providers, and sponsors. Sponsoring encompasses not only a distribution of pre-produced multimedia content (e.g., by offering wallpapers), Java games, or ringtones based on a product, but also mobile multimedia services.

Mobile multimedia poses several problems for the user. First, how can multimedia content of high quality be produced with a mobile device. Cameras in mobile telephones are getting better with each device generation; still the achievable resolutions and framerates are behind the capabilities of current digital cameras. Second, how can multimedia content be stored on or transmitted from a mobile device. Multimedia data, sophisticated compression algorithms notwithstanding, is still large, especially when compared to simple text messages. External media, such as memory cards or the Universal Media Disk (UMD), can be used to a certain degree to archive and distribute data. They do not provide a solution for spreading this data via a wireless network to other users. Third, editing multimedia content on mobile devices is nearly impossible. Tools exist for basic image manipulation, but again their functionality is reduced and handling is complex.

Kindberg, Spasojevic, Fleck, and Sellen (2005) found in their study that camera phones are primarily used to capture still images for sentimental, personal reasons. These pictures are intended to be shared, and sharing mostly takes place in face-to-face meetings. Sending a picture via e-mail or MMS to a remote phone occurred only in 20% of all taken pictures. Therefore, one possible conclusion is that users have a desire to share personal moments with others, but current cost structures prohibit remote sharing and foster transmission of pictures via Bluetooth or infrared.

V-card sets out to address these problems by providing a message-hub for sublimated multimedia messaging. With V-card, users can create personalized, high-quality multimedia messages (MMS) and send those to their friends. Memory constraints are evaded by implementing streaming audio and video where applicable. V-cards can consist of pictures, audio, video, and MIDlets (Java 2 Micro-Edition applications). Experience with mobile greetingcards show that users are interested in high-quality content and tend to forward them to friends and relatives. This viral messaging effect increases utilisation of the V-card system and spreads the information of the sponsor. Haig (2002, p. 35) lists advice for successful viral marketing campaigns, among them:

- Create of a consumer-to-consumer environment
- Surprise the consumers
- Encourage interactivity

A V-card message is sponsored, but originates from one user and is sent to another user. Sponsoring companies therefore are actually not included in the communication process, as they are neither a sender nor a receiver. V-card is thus a true consumer-to-consumer environment. It also can be expected for the near future that high quality content contains an element of surprise, as it exceeds the current state of the art of text messaging. Interactivity is fostered by interesting content, which is passed on, but also by interactive elements like MIDlet games.

Additionally, Lippert (2002) presents a "4P strategy" for mobile advertising, listing four characteristics a marketing campaign must have:

- Permitted
- Polite
- Profiled
- Paid

"Permitted" means a user must agree to receive marketing messages. With V-card, the originator of the MMS is not a marketing company but another user, therefore the communication itself is emphasized, not the marketing proposition. Legal aspects regarding permissions are discussed detailed below. Marketing messages should also be "polite," and not intrusive. Again, the enhanced

multimedia communication between the sender and the receiver is in the foreground, not the message from the sponsor.

"Profiling" marketing tools enables targeted marketing and avoids losses due to non-selective advertising. Even if V-card itself is unable to match a sponsor to users, since users do not create a profile with detailed personal data, profiling is achieved by a selection process of the sender. As messages can be enhanced by V-card with media related to a specific sponsor, by choosing the desired theme the sender tailors a message to the interests of himself and the receiver. Usually, marketing messages should provide a target group with incentives to use the advertised service; the recipients need to get "paid." With V-card, sponsors "pay" both users by reducing the costs of a message and by providing high quality multimedia content.

V-CARD ARCHITECTURE

V-Card Core Architecture

Figure 1 shows the V-card core architecture and illustrates the workflow. First, the user with a mobile device requests a personalised application via the SMSC or Multimedia Messaging Service Centre (MMSC), which are part of the mobile network infrastructure. The message is passed on to the V-card core, where the connector decides which application has been called.

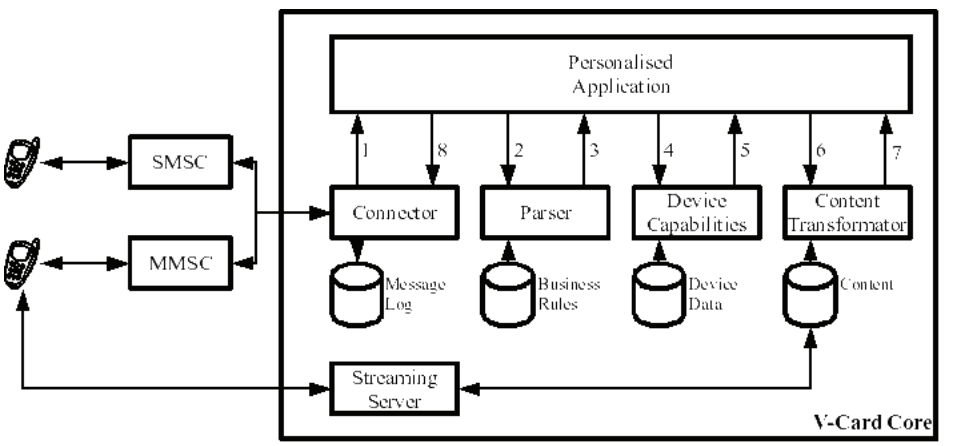
After the request is passed on to the appropriate application (1), it is logged in the message log. A parser receives the message (2), extracts the relevant data for customisation, and returns this data (3)–this could include the receiver's phone number, the name of the sender or a message. Then, the capabilities of the receiving phone are queried from a database which holds all relevant data (4+5) like display size, number of colours, supported video and audio codecs.

Finally, the application transmits all the data gathered to the content transformator. Here, the pre-produced content is tailored with the input delivered by the user according to the capabilities of the device (6+7). The result is then sent via the connector (8) to the receiving user. Since the personalised applications and the data are separated, new applications can be easily created.

V-Card Streaming Technology

Since video content can not be stored directly on a mobile device due to memory limitations, a streaming server supplies video data to the device where the video is played, but not stored with

Figure 1. V-Card core architecture



the exception of buffered data, which is stored temporarily to compensate for varying network throughput. Streaming video and audio to mobile devices can be utilized for various services (e.g., for mobile education) (Lehner, Nösekabel, & Schäfer 2003). In the case of V-card, the MMS contains a link to adapted content stored on the content server. This link can be activated by the user and is valid for a certain amount of time. After the link has expired, the content is removed from the content server to conserve memory.

Currently, there are two streaming server solutions available for mobile devices. RealNetworks offers the HELIX server based on the ReadMedia format. RealPlayer, a client capable of playing back this format, is available for Symbian OS, Palm OS 5, and PocketPC for PDAs. Additionally, it is available on selected handsets, including the Nokia 9200 Series Communicators and Nokia Series 60 phones, including the Nokia 7650 and 3650. The other solution is using a standardized 3GPP-stream based on the MPEG4 format, which can be delivered using Apples Darwin server.

An advantage of implementing streaming technology for mobile multimedia is the fact that only a portion of the entire data needs to be transmitted to the client, and content can be played during transmission. Data buffers ensure smooth playback even during short network interruptions or fluctuations in the available bandwidth. As video and audio are time critical, it is necessary that the technologies used are able to handle loss of data segments, which do not arrive in time (latency) or which are not transmitted at all (network failure). GPRS and HSCSD connections allow about 10 frames per second at a resolution of 176 by 144 pixel (quarter common intermediate format QCIF resolution) when about 10 KBit per second are used for audio. Third generation networks provide a higher bandwidth, leading to a better quality and more stable connectivity.

A drawback of streaming is the bandwidth requirement. For one, the bandwidth should be constant; otherwise the buffered data is unable to compensate irregularities. Next, the available bandwidth directly influences the quality that can be achieved — the higher the bandwidth, the better the quality. Third, a transfer of mobile data can be expensive. A comparison of German network providers in 2003 showed that 10 minutes of data transfer at the speed of 28 KBit per second (a total amount of 19 Megabyte) resulted in costs ranging from 1 Euro (time-based HSCSD tariff) up to 60 Euro (packet-based GPRS by call tariff).

V-Card Examples

Figures 2 demonstrates a picture taken with the camera of a mobile device, rendered into a video clip by the V-card core. Figure 3 combines pictures and text from the user with video and audio content from the V-card hub. Figure 4 shows how simple text messages can be upgraded when a picture and an audio clip are added to create a multimedia message.

Since sponsoring models either influence the choice of media used to enhance a message, or can be included as short trailers before and after the actual message, users and sponsors can choose from a wide variety of options best suited for their needs.

LEGAL ASPECTS

It should be noted that the following discussion focuses on an implementation in Germany and today (2005Q1)–although several EU guidelines are applicable in this area there are differences in their national law implementations and new German and EU laws in relevant areas are pending.

Legal aspects affect V-card in several areas: consumer information laws and rights of withdrawal, protection of minors, spam law, liability, and privacy. A basic topic to those subjects is the classification of V-card among "Broadcast Service" ("Mediendienst"), "Tele Service" ("Teledienst"), and "Tele Communication Service"

Figure 2. V-Card with picture in video

Figure 3. V-Card with picture and text in video

Figure 4. V-Card with text in picture and audio

("Telekommunikationsdienst"). According to § 2 Abs. 2 Nr. 1 and § 2 Abs. 4 Nr. 3 Teledienstegesetz (TDG) V-card is not a "Broadcast Service" and based on a functional distinction (see e.g., Moritz/Scheffelt in Hoeren/Sieber, 4, II, Rn. 10) V-card is presumed to be a "Tele Service."

Consumer information laws demand that the customer is informed on the identity of the vendor according to Art. 5 EU Council Decision 2000/31/EC, to § 6 TDG and to § 312c Bürgerliches Gesetzbuch (BGB) (e.g., on certain rights he has with regard to withdrawal). The fact that V-card might be free of charge for the consumer does not change applicable customer protection laws as there is still a (one-sided) contract between the costumer and the provider (see e.g., Bundesrat, 1996, p. 23). Some of these information duties have to be fulfilled before contract and some after. The post-contract information could be included in the result MMS and the general provider information and the pre-contract information could be included in the initial advertisements and/or a referenced WWW- or WAP-site. Art. 6 EU Council Decision 2000/31/EC and § 7 TDG demand a distinction between information and adverts on Web sites and can be applicable, too. A solution could be to clearly communicate the fact that the V-card message contains advert (e.g., in the subject) (analogue to Art. 7(1) EU Council Decision 2000/31/EC, although this article is not relevant in Germany). The consumer might have a withdrawal right based on § 312d (1) BGB on which he has to be informed although the exceptions from § 312c (2) 2nd sentence BGB or § 312d (3) 2 BGB could be applicable. With newest legislation the consumer has to be informed on the status of the withdrawal rights according to § 1 (1) 10 BGB-Informationspflichtenverordnung (BGB-InfoV), whether he has withdrawal rights or not.

§ 6 Abs. 5 Jugendmedienschutzstaatsvertrag (JMStV) bans advertisements for alcohol or tobacco which addresses minors, § 22 Gesetz über den Verkehr mit Lebensmitteln, Tabakerzeugnissen, kosmetischen Mitteln und sonstigen

Bedarfsgegenständen (LMBG) bans certain kinds of advertisements for tobacco, Art. 3(2) EU Council Decision 2003/33/EC (still pending German national law implementation) bans advertisements for tobacco in Tele Services. Therefore a sponsor with alcohol or tobacco products will be difficult for V-card. Sponsors with erotic or extreme political content will also be difficult according to § 4, 5 and 6(3) JMStV. § 12(2) 3rd sentence Jugendschutzgesetz (JuSchG) demands a labelling with age rating for content in Tele Services in case it is identical to content available on physical media. Since V-card content will most of the time special-made and therefore not available on physical media, this is not relevant.

The e-mail spam flood has led to several EU and national laws and court decisions trying to limit spam. Some of these laws might be applicable for mobile messaging and V-card, too. In Germany a new § 7 in the Gesetz gegen den unlauteren Wettbewerb (UWG) has been introduced. The question in this area is whether it can be assumed that the sent MMS is ok with the recipient (i.e., if an implied consent can be assumed). Besides the new § 7 UWG if the implied consent cannot be assumed a competitor or a consumer rights protection group could demand to stop the service because of a "Eingriff in den eingerichteten und ausgeübte Gewerbebetrieb" resp. a "Eingriff in das Allgemeine Persönlichkeitsrecht des Empfängers" according to §§ 1004 resp. 823 BGB.

Both the new § 7 UWG and previous court decisions focus on the term of an unacceptable annoyance or damnification which goes along with the reception of the MMS. The highest German civil court has ruled in a comparable case of advert sponsored telephone calls (BGH reference I ZR 227/99) that such an implied consent can be assumed under certain conditions e.g. that the communication starts with a private part (and not with the advertisement) and that the advertisement is not a direct sales pitch putting psychological pressure on the recipient (see e.g., Lange 2002, p. 786). Therefore if a V-card message consists of a private part together with attractive and entertaining content and a logo of the sponsor the implied consent can be assumed. The bigger the advertisement content part is the likelier it is that the level of a minor annoyance is crossed and the message is not allowed according to § 7 UWG (see e.g., Harte-Bavendamm & Henning-Bodewig, 2004, § 7, Rn. 171).

If users use the V-card service to send unwelcome messages to recipients V-card could be held responsible as an alternative to the user from whom the message originated. A Munich court (OLG München reference 8 U 4223/03) ruled in this direction in a similar case of an e-mail news letter service however focusing on the fact that the service allowed the user to stay anonymously. This is not the case with the mobile telephone numbers used in V-card, which are required to be associated with an identified person in Germany. In addition to this the highest German court has in some recent decisions (BGH I ZR 304/01, p. 19 and I ZR 317/01, p. 10) narrowed the possibilities for a liability as an alternative by limiting the reasonable examination duties.

Manual filtering by the V-card service is a violation of communication secrecy and therefore not allowed (see e.g., Katernberg, 2003). Automatic filtering must not result in message suppression since this would be illegal according to German martial law § 206 (2) 2 Strafgesetzbuch.

The obligation to observe confidentiality has in Germany the primary rule that data recording is not allowed unless explicitly approved (§ 4 Bundesdatenschutzgesetz). Log files would therefore not be allowed with an exception for billing according to § 6 Gesetz über den Datenschutz bei Teleddiensten (TDDSG). These billing logs must not be handed over to third parties likely also including the sponsor.

As a conclusion, it can be noted that an innovative service like V-card faces numerous legal problems. During the project, however, it became clear that all these requirements can be met by an appropriate construction of the service.

EVALUATION OF V-CARD

Since V-card also has the ability to transmit personalised J2ME applications via MMS (see Figure 5 for an example), it surpasses the capabilities of pure MMS messages creating added value for the user, which normally do not have the possibility to create or modify Java programs. One example is a sliding puzzle where, after solving the puzzle, a user may use the digital camera of the mobile device to change the picture of the puzzle. After the modification, the new puzzle can then be send via V-card to other receivers.

Still, as previously mentioned, V-card requires a MMS client. It can therefore be regarded as an enhancement or improvement for MMS communication and is as such a competitor to the "normal" MMS. Hence, an evaluation framework should be usable to measure the acceptance of both "normal" MMS messaging and "enhanced" V-card messaging, creating results that can be compared with each other to determine the actual effect of the added value hoped to be achieved with V-card. While extensive research exists regarding PC-based software, mobile applications currently lack comprehensive methods for creating such evaluations. Therefore, one possible method was developed and applied in a fieldtest to evaluate V-card (Lehner, Sperger, & Nösekabel, 2004).

At the end of the project on June 3, 2004, a group of 27 students evaluated the developed V-card applications in a fieldtest. Even though the composition and size of the group does not permit to denote the results as representative, tendencies can be identified. The statistical overall probability of an error is 30%, as previously mentioned.

The questionnaire was implemented as an instrument to measure results. To verify the quality and reliability of the instrument, three values were calculated based on the statistical data. The questionnaire achieved a Cronbach alpha value of 0.89—values between 0.8 and 1.0 are regarded as acceptable (Cronbach, 1951). The split-half correlation, which measures the internal consistency

Figure 5. V-card with MIDlet puzzle application

of the items in the questionnaire, was calculated to be 0.77 with a theoretical maximum of 1.0. Using the Spearman-Brown formula to assess the reliability of the instrument, a value of 0.87 was achieved. Again, the theoretical maximum is 1.0. Therefore, the questionnaire can be regarded to be statistically valid and reliable.

One result of the fieldtest was that none of the students encountered difficulties in using any of the V-card applications, even though the usability of the mobile phone used in the fieldtest was regarded as less than optimal.

Overall 66% of the students thought that V-card was easy to use, 21% were undecided. It is very likely that the sample group leaned towards a negative or at least neutral rating as the usability of the end device was often criticised. This factor can not be compensated by the programmers of the mobile application. Another indicator for this rationale is the comparison with the results for the MMS client. Here, 75% of the group agreed to this statement, which is an increase of 9%. The similarity of the results suggests that also the rating for the usability of the MMS client was tainted by the usability of the device.

No uniform opinion exists regarding sponsored messages by incorporating advertising. Forty-two

percent of the students would accept advertisements if that would lower the price of a message. Thirty-seven percent rejected such a method. The acceptable price for a V-card message was slightly lower compared to that of a non-sublimated MMS, which on the other hand did not contain content from a sponsor.

An important aspect for the acceptance of mobile marketing is the protection of privacy. In this area the students were rather critical. Sixty-three percent would reject to submit personal data to the provider of V-card. Since this information was not necessary to use V-card, only 17% of the sample group had privacy concerns while using V-card.

The mobile marketing component was perceived by all participants and was also accepted as a mean to reduce costs. This reduction should benefit the user, therefore a larger portion of the sample group rejected for V-card the idea for increased cost incurred by a longer or more intensive usage (88% rejected this for V-card, 67% for MMS).

As already addressed, the pre-produced content of V-card helped 50% of the users to achieve the desired results. The portion rejecting this statement for V-card was 25%, which is higher than the 8% who rejected this statement for MMS. This leads to the conclusion that if the pre-produced content is appropriate in topic and design for the intended message, it contributes to the desired message. However, it is not possible to add own content if the pre-produced content and the intention of the sender deviate. The user is therefore limited to the offered media of the service provider.

Overall, the ratings for V-card by the students were positive. Marketing messages, which were integrated into the communication during the fieldtest, were not deemed objectionable. The usability of V-card was also rated high. Main points that could be addressed during the actual implementation in the mobile market should include privacy and cost issues.

CONCLUSION

The new messaging service MMS has high potential and is being widely adopted today, although prices and availability are far from optimal. Mostly young people tend to use the fashionable messages which allow much richer content to be sent instantly to a friend's phone. This young user group is especially vulnerable to debts due to their mobile phones though, or they have prepaid subscriptions letting them only send a very limited number of messages. By incorporating a sponsor model in V-card, this user group will be able to send a larger number of messages with no additional cost and thereby offering advertising firms a possibility to market their services and goods. For those users that are not as price sensitive, the large amount of professional media and the ease of the message-composition will be an incentive to use the service. The added value of the service should be a good enough reason to accept a small amount of marketing in the messages. Since V-card offers the sender and receiver an added value, the marketing message will be more acceptable than other forms of advertising where only the sender benefits from the advertisement.

Another advantage of V-card is the fact that the system takes care of the administration and storing of professional media and the complicated formatting of whole messages, thus taking these burdens from the subscriber. At the same time, V-card offers marketers a new way to reach potential customers and to keep in dialogue with existing ones. The ease of sending such rich content messages with a professional touch to a low price or even no cost at all will convince subscribers and help push 3G networks.

Overall, it can be expected that marketing campaigns will make further use of mobile multimedia streaming, aided by available data rates and the increasing computing power of mobile devices. Continuous media (video and audio), either delivered in real-time or on demand, will possibly become the next entertainment paradigm for a mobile community.

KEY TERMS

MMS: Multimedia message service: Extension to SMS. A MMS may include multimedia content (videos, pictures, audio) and formatting instructions for the text.

Multimedia: Combination of multiple media, which can be continuous (e.g., video, audio) or discontinuous (e.g., text, pictures).

SMS (Short Message Service): text messages that are sent to a mobile device. A SMS may contain up to 160 characters with 7-bit length, longer messages can be split into multiple SMS.

Streaming: Continuous transmission of data primarily used to distribute large quantities of multimedia content.

UMTS (Universal Mobile Telecommunications System): 3rd generation network, providing higher bandwidth than earlier digital networks (e.g., GSM, GPRS, or HSCSD).

Chapter 6.5
Mobile Multimedia for Commerce

P.M. Melliar-Smith
University of California, Santa Barbara, USA

L.E. Moser
University of California, Santa Barbara, USA

INTRODUCTION

The ready availability of mobile multimedia computing and communication devices is driving their use in commercial transactions. Mobile devices are lightweight and wireless so users can carry them and move about freely. Such devices include cell phones, PDAs and PCs equipped with cellular modems.

In the history of man, mobile commerce was the conventional form of commerce but during the twentieth century, it was superseded by fixed locations as a result of non-mobile infrastructure (stores and offices) and the ability of customers to travel. With modern mobile infrastructure, commerce can be conducted wherever the customer is located, and the sales activity can occur wherever and whenever it is convenient for the customer.

BACKGROUND

Mobile computing and communication devices, based on cellular communication, are a relatively recent innovation. Multimedia computing and communication, including video, audio, and text, are available for mobile devices but are limited by small screens, low bandwidth, and high transmission costs. These limitations distinguish mobile multimedia computing and communication from desktop multimedia computing and communication over the Internet, including WiFi, and dictate a somewhat different approach.

Mobile commercial processes are still largely experimental and are not yet well established in practice. Some researchers (Varshney, 2000) have projected that the use of mobile devices in consumer-to-business transactions will increase as much as 40%. Cautious consumers, inadequate mobile devices, security concerns, and undevel-

oped business models and procedures currently limit the use of mobile multimedia devices for commercial transactions.

Because mobile multimedia commerce using mobile devices is a new and developing field, there is relatively little available information, and that information is scattered. Early discussions of mobile commerce can be found in Senn (2000) and Varshney (2000). The i-mode service (Kinoshita, 2002; Lane, 2002) for mobile commerce has achieved some commercial success, within the limitations of existing devices and protocols.

LIMITATIONS OF THE MOBILE DEVICE

Cellular communication is wireless communication between mobile devices (e.g., cell phones, PDAs, and PCs) and fixed base stations. A base station serves mobile devices within a relatively small area of a few square miles (called a cell). The base stations are interconnected by fixed telecommunication infrastructure that provides connection with other telecommunication systems. When a mobile device passes from the cell of one base station to that of another, the first base station hands off communication with the device to the other, without disrupting communication.

Mobile devices are inherently more limited than fixed devices, but these limitations, appropriately recognized and accommodated, do not preclude their use in commerce (Buranatrived, 2002; Lee & Benbasat, 2003). Mobile devices have restricted display, input, print, and communication capabilities. The impact of these limitations depends on the user. A professional mobile sales representative needs better display, input, and print capabilities than many other kinds of users.

Mobile devices, such as cell phones and PDAs, have very small displays (less than 15 cm) that are likely to remain small, a limitation imposed by the need to insert the device into a pocket or purse, or to carry the device on a belt, and also by battery consumption. Such displays are inadequate for viewing detailed textual or graphical material. In an environment that is saturated with television, video, animated Web pages, and so forth, impressive multimedia sales presentations are even more important. Therefore, a mobile sales representative most likely will carry a notebook computer with a high-resolution display of 30 cm to 50 cm, and might even carry a projection display, which imposes little limitation on the material to be displayed.

The input capabilities of current mobile devices, such as cell phones and PDAs, are currently primitive and difficult to use for commercial activities. When natural language voice input is improved, the input of more complex requests, responses, and textual material will be possible. Substantial advances in speech recognition and natural language processing are necessary, and substantial increases in processing power and battery capacity are required before this promise can be realized.

Mobile devices are unlikely to provide printed output, but a mobile sales representative will likely carry a portable printer with which to create documents for the customer. Alternatively, such documents might be transferred directly between the mobile sales representative's device and the customer's device, using a cellular, infrared, bluetooth, or other wireless connection, without a physical paper record.

Storage capacity is not really a limitation for mobile commerce; hard disk capacities of many Gbytes are available for mobile devices. Similarly, the bandwidth of cellular communication links is sufficient for commercial interactions; however, the cost of transmitting detailed graphics over a cellular link is relatively high. Therefore, a mobile commercial sales representative will likely carry, on hard disk or CD, presentations and catalogs that contain detailed graphics or video, so that they do not need to be downloaded over an expensive wireless connection.

Typical mobile devices operate with low bandwidth, too low to allow effective display of video or Web pages. Remarkable efforts have been made with i-mode services (Kinoshita, 2002; Lane, 2002) to achieve effective mobile commerce, despite bandwidth limitations. The 3G networks currently being deployed provide sufficient bandwidth for display of video and Web pages. However, the high cost of cellular communication remains a significant limitation on activities that require large amounts of information to be transmitted. Mobile commercial activities need to operate with minimal or intermittent connections and with activities conducted while disconnected.

Currently, battery power and life are also significant limitations on mobile multimedia devices, restricting the availability of processing, display, and communication. However, small, light, mobile, alcohol-based fuel cells are in prototype and demonstration. When substantial demand develops for more powerful mobile multimedia devices, more powerful batteries will become available.

NEEDS OF USERS

It is important to distinguish between the needs of sellers and buyers and, in particular, the needs of:

- Professional mobile sellers;
- Professional mobile buyers;
- Convenience purchasers.

The popular concept of mobile commerce focuses on the buyer, but buyers are motivated by convenience, and attractive, effective capabilities are required to achieve significant adoption by buyers. In contrast, sellers are motivated by need, and they are more likely to be early adopters of novel technology.

Needs of Mobile Sellers

Professional mobile sellers include insurance agents, contractors, and other sales people who make presentations on the customers' premises. In the Internet era, with customers who do not need to visit a seller to make a purchase, sellers no longer need to wait for customers but need to become mobile to find customers wherever they can be found. Mobile sellers require support for contact information, appointments, scheduling, and reminders. PC-based tools provide such services, although their human interfaces are not appropriate for mobile devices. Mobile sales people might also use Customer Relationship Management (CRM) software that likely will run on a central server and will be accessed remotely by a seller using a cellular Internet connection.

The most demanding aspect of the work of a mobile sales person is the presentation to the customer. A mobile sales person lacks the large physical stock and demonstration models available at a fixed site but, instead, must depend on a computer-generated display of the product. An impressive multimedia presentation is essential for selling in an environment that is saturated with television, video, animated Web pages, and the like. Thus, a mobile sales person can be expected to carry a display device (a laptop computer or a projection display), with presentations and catalogs stored on hard disk or CD. Significant effort is required to make a computer-hosted catalog as convenient to use as a conventional paper catalog, but a large computer-hosted catalog is more convenient to carry, can be searched, can contain animations, and can be updated more easily and more frequently.

Access to a catalog or other presentation material hosted on a central server is unattractive because of the cost and time of downloading detailed graphic presentations over an expensive wireless link. However, a mobile sales person needs a cellular Internet communication with the central server to query inventory, pricing, and delivery;

to enter sales orders; to make reservations; and to schedule fulfillment of the sale. The mobile sales person also needs to generate proposals and contracts on the mobile device and print them for the customer. Many customers will accept electronic delivery of proposals and exchange of contracts; however, some customers will require paper copies. and, thus, the mobile sales person must carry a printer.

In summary, a laptop computer with a cellular modem and a portable printer, possibly augmented by a projection display for multimedia presentations, can satisfy the needs of a mobile sales person.

Needs of Mobile Buyers

The direct mobile buyer analog of the mobile sales person, a buyer who visits sellers to purchase goods, such as a buyer who visits ranchers to purchase livestock or visits artists to purchase paintings, is unlikely to develop. Such sellers have already discovered the use of the Internet to sell their products at higher prices than such a visiting buyer would offer.

Professionals who need to purchase while mobile include contractors and travelers. When using a mobile device such as a cell phone or PDA, they are likely to limit their activities to designation of items and quantities, delivery address and date, and payment information. They are unlikely to use such mobile devices to browse catalogs and select appropriate merchandise, because of the inadequate display and input capabilities of the devices and because of the cost of cellular Internet connections. It is essential to analyze carefully the model of transactions in a specific field of commerce, and the software and interactions needed to support that model (Keng, 2002).

Current cell phones and PDAs are barely adequate in their input and output capabilities for purchase of items in the field (Buranatrived, 2002; Lee, 2003). The small display size of portable mobile devices is unlikely to change soon but can be compensated to some extent by Web pages that are designed specifically for those devices. Such mobile-friendly Web pages must be designed not only to remove bandwidth-hogging multimedia and graphics and to reduce the amount of information presented, but also to accommodate a professional who needs to order items with minimum interaction.

Web pages designed originally for high-resolution desktop computers can be downgraded automatically, so that they require less transmission bandwidth. However, such automated downgrading does not address the abbreviated interaction sequences needed by a professional using a mobile device. Most professionals would prefer to make a conventional phone call to purchase goods, rather than to use an existing mobile device.

Mobile devices such as cell phones and PDAs have inadequate input capabilities for such mobile buyers, particularly when they are used in restricted settings such as a building site or a moving truck. This problem will be alleviated by natural language voice input when it becomes good enough. Until then, professional mobile buyers might prefer to select a small set of items from the catalog, download them in advance to the mobile device using a fixed infrastructure communication link, and use a retrieval and order program specifically designed for accessing the downloaded catalog items on the mobile device.

Needs of Convenience Purchasers

Convenience purchasers expect simpler human interfaces and lower costs than professional sellers or buyers (Tarasewich, 2003). For the convenience purchaser, because of the poor human interfaces of current mobile devices, a purely digital mobile commercial transaction is substantially less convenient and satisfying than visiting a store, making a conventional telephone call, or using the better display, easier interfaces, and lower costs of a PC to purchase over the Internet.

Convenience purchasers are most likely to purchase products that are simple and highly standardized, or that are needed while mobile. Nonetheless, mobile devices can facilitate commercial transactions in ways other than direct purchase. For example, a mobile device associated with its human owner can be used to authorize payments in a way that is more convenient than a credit card (Ogawara, 2002).

The mobile device is usually thought of as facilitating commercial transactions through mobility in space, but locating a customer in space is also an important capability (Bharat, 2003). However, location-aware services typically benefit the seller rather than the mobile purchaser, and somewhat resemble spam. A mobile device also can be used to facilitate the collection of information through time, particularly if the device is continuously present with and available to its user.

ENABLING TECHNOLOGY FOR MOBILE MULTIMEDIA

The Wireless Application Protocol, Wireless Markup Language, and Wireless Security Transport Layer discussed next are used in commercial mobile devices and enable the use of mobile multimedia for commerce.

Wireless Application Protocol

The Wireless Application Protocol (WAP) is a complex family of protocols (WAP Forum, 2004), for mobile cell phones, pagers, and other wireless terminals. WAP provides:

- Content adaptation, using the Wireless Markup Language (WML) discussed later, and the WMLScript language, a scripting language similar to JavaScript that is oriented toward displaying pages on small low-resolution displays.
- Reliability for display of Web pages provided by the Wireless Datagram Protocol (WDP) and the Wireless Session Protocol (WSP) to cope with wireless connections that are rather noisy and unreliable.
- Efficiency, provided by the WDP and the WSP through data and header compression to reduce the bandwidth required by the applications.
- Integration of Web pages and applications with telephony services provided by the WSP and the Wireless Application Environment (WAE), which allows the creation of applications that can be run on any mobile device that supports WAP.

Unfortunately, WAP's low resolution and low bandwidth are traded off against convenience of use. Because screens are small and input devices are primitive, selection of a service typically requires inconvenient, confusing, and time-consuming steps down a deep menu structure. Successful applications have been restricted to:

- Highly goal-driven services aimed at providing immediate answers to specific problems, such as, "My flight was canceled; make a new airline reservation for me."
- Entertainment-focused services, such as games, music, and sports, which depend on multimedia.

As mobile devices become more capable, WAP applications will become easier to use and more successful.

Wireless Markup Language (WML)

The Wireless Markup Language (WML), which is based on XML, describes Web pages for low-bandwidth mobile devices, such as cell phones. WML provides:

- Text presentation and layout – WML includes text and image support, including a variety of format and layout commands, generally simple and austere, as befits a small screen.
- Deck/card organizational metaphor – in WML, information is organized into a collection of cards and decks.
- Intercard navigation and linking – WML includes support for managing the navigation between cards and decks with reuse of cards to minimize markup code size.
- String parameterization and state management – WML decks can be parameterized using a state model.
- Cascading style sheets – these style sheets separate style attributes for WML documents from markup code, reducing the size of the markup code that is transmitted over a cellular link and that is stored in the memory of the mobile device.

WML is designed to accommodate the constraints of mobile devices, which include the small display, narrow band network connection, and limited memory and computational resources. In particular, the binary representation of WML, as an alternative to the usual textual representation, can reduce the size of WML page descriptions.

Unfortunately, effective display of pages on low-resolution screens of widely different capabilities requires WML pages that are specifically, individually, and expensively designed for each different mobile device, of which there are many. In contrast, HTML allows a single definition for a Web page, even though that page is to be viewed using many kinds of browsers and displays.

Wireless Transport Security Layer

Security is a major consideration in the design of systems that provide mobile multimedia for commerce. The Wireless Transport Security Layer (WTSL) aims to provide authentication, authorization, confidentiality, integrity, and non-repudiation (Kwok-Yan, 2003; WAPForum, 2004; Wen, 2002). Major concerns are:

- Disclosure of confidential information by interception of wireless traffic, which is addressed by strong encryption.
- Disclosure of confidential information, including location information within the wireless service provider's WAP gateway, which can be handled by providing one's own gateway, although most users might prefer to rely on the integrity of the wireless service provider.
- Generation of transactions that purport to have been originated by a different user, which can be handled by Wireless Identity Modules (WIMs). A WIM, which is similar to a smart card and can be inserted into a WAP-enabled phone, uses encryption with ultra-long keys to provide secure authentication between a client and a server and digital signatures for individual transactions. WIMs also provide protection against interception and replay of passwords.
- Theft and misuse of the mobile device, or covert Trojan horse code that can extract encryption keys, passwords, and other confidential information from the mobile device, which is handled by WIMs that can be but probably will not be removed from the mobile device for safe keeping, and that can themselves be lost or stolen.

WTSL is probably provides adequate security for most commercial mobile multimedia transactions, and is certainly more secure than the vulnerable credit card system that is used today for many commercial transactions.

CONCLUSION

Mobile multimedia will be a significant enabler of commerce in the future, as mobile devices become more capable, as multimedia provides

more friendly user interfaces and experiences for the users, and as novel business models are developed. Great care must be taken to design services for mobile multimedia commerce for the benefit of the mobile user rather than the sellers of the service. Natural language voice input and intelligent software agents will increase the convenience of use and, thus, the popularity of mobile devices for commercial transactions.

It is not easy to predict innovations in commercial transactions; the most revolutionary and successful innovations are the most difficult to predict, because they deviate from current practice. In particular, mobile multimedia devices can be expected to have major, but unforeseeable, effects on social interactions between people, as individuals and in groups. Novel forms of social interaction will inevitably engender new forms of commercial transactions.

KEY TERMS

Cellular Communication: Wireless communication between mobile devices (e.g., cell phones, PDAs, and PCs) and fixed base stations. The base stations serve relatively small areas of a few square miles (called cells) and are interconnected by fixed telecommunication infrastructure that provides connection with other telecommunication systems. As a mobile device passes from one cell to another, one base station hands off the communication with the device to another without disrupting communication.

Mobile Commerce: Commercial transactions in which at least one party of the transaction uses a mobile wireless device, typically a cell phone, a PDA, or a PC equipped with a cellular modem. A PC can conduct a commercial Internet transaction using a WiFi connection to a base station, but because WiFi connections currently provide limited mobility, for this article, WiFi transactions are regarded as standard Internet transactions rather than mobile commerce.

Mobile Devices: Computing and communication devices, such as cell phones, PDAs, and PCs equipped with cellular modems. Mobile devices are lightweight and wireless so users can carry them and move about freely.

Mobile Multimedia: Use of audio and/or video in addition to text and image pages. The low bandwidth and high cost of mobile cellular connections discourage the use of video. Spoken natural language input and output is a promising but difficult approach for improving the ease of use of mobile devices for commercial transactions.

Wireless Application Protocol (WAP): The Wireless Application Protocol is an application-level communication protocol that is used to access services and information by hand-held devices with low-resolution displays and low bandwidth connections, such as mobile cell phones.

Wireless Markup Language (WML): A Web page description language derived from XML and HTML, but specifically designed to support the display of pages on low-resolution devices over low-bandwidth connections.

Wireless Transport Security Layer (WTSL): A high-security, low-overhead layer that operates above WDP and below WSP to provide authentication, authorization, confidentiality, integrity, and non-repudiation.

Chapter 6.6
Business Model Typology for Mobile Commerce

Volker Derballa
Universität Augsburg, Germany

Key Pousttchi
Universität Augsburg, Germany

Klaus Turowski
Universität Augsburg, Germany

ABSTRACT

Mobile technology enables enterprises to invent new business models by applying new forms of organization or offering new products and services. In order to assess these new business models, there is a need for a methodology that allows classifying mobile commerce business models according to their typical characteristics. For that purpose a business model typology is introduced. Doing so, building blocks in the form of generic business model types are identified, which can be combined to create concrete business models. The business model typology presented is conceptualized as generic as possible to be generally applicable, even to business models that are not known today.

INTRODUCTION

Having seen failures like WAP, the hype that was predominant for the area of mobile commerce (MC) up until the year 2001 has gone. About one year ago however, this negative trend has begun to change again. Based on more realistic expectations, the mobile access and use of data, applications and services is considered important by an increasing number of users. This trend becomes obvious in the light of the remarkable success of mobile communication devices. Substantial growth rates are expected in the next years, not only in the area of B2C but also for B2E and B2B. Along with that development go new challenges for the operators of mobile services resulting in re-assessed validations and alterations of existing business models and the creation of new business

models. In order to estimate the economic success of particular business models, a thorough analysis of those models is necessary. There is a need for an evaluation methodology in order to assess existing and future business models based on modern information and communication technologies. Technological capabilities have to be identified as well as benefits that users and producers of electronic offers can achieve when using them.

The work presented here is part of comprehensive research on mobile commerce (Turowski & Pousttchi, 2003). Closely related is a methodology for the qualitative assessment of electronic and mobile business models (Bazijanec, Pousttchi, & Turowski, 2004). In that work, the focus is on the added value for which the customers is ready to pay. The theory of informational added values is extended by the definition of technology-specific properties that are advantageous when using them to build up business models or other solutions based on information and communication techniques. As mobile communication techniques extend Internet technologies and add some more characteristics that can be considered as additional benefits, a own class of technology-specific added values is defined and named mobile added values (MAV), which are the cause of informational added values. These added values based on mobility of mobile devices are then used to assess mobile business models.

In order to be able to qualitatively assess mobile business models, those business models need to be unambiguously identified. For that purpose, we introduce in this chapter a business model typology. Further, the business model typology presented here is conceptualized as generic as possible, in order to be robust and be generally applicable — even to business models that are not known today. In the following we are building the foundation for the discussion of the business model typology by defining our view of MC. After that, alternative business model typologies are presented and distinguished from our approach, which is introduced in the subsequent section. The proposed approach is then used on an existing MC business model. The chapter ends with a conclusion and implications for further research.

BACKGROUND AND RELATED WORK

Mobile Commerce: A Definition

Before addressing the business model typology for MC, our understanding of MC needs to be defined. If one does agree with the Global Mobile Commerce Forum, mobile commerce can be defined as "the delivery of electronic commerce capabilities directly into the consumer's device, anywhere, anytime via wireless networks." Although this is no precise definition yet, the underlying idea becomes clear. Mobile commerce is considered a specific characteristic of electronic commerce and as such comprises specific attributes, as for example the utilization of wireless communication and mobile devices. Thus, mobile commerce can be defined as every form of business transaction in which the participants use mobile electronic communication techniques in connection with mobile devices for initiation, agreement or the provision of services. The concept mobile electronic communication techniques is used for different forms of wireless communication. That includes foremost cellular radio, but also technologies like wireless LAN, Bluetooth or infrared communication. We use the term mobile devices for information and communication devices that have been developed for mobile use. Thus, the category of mobile devices encompasses a wide spectrum of appliances. Although the laptop is often included in the definition of mobile devices, we have reservations to include it here without precincts due to its special characteristics: It can be moved easily, but it is usually not used during that process. For that reason we argue that the laptop can only be seen to some extend as amobile device.

Related Work

Every business model has to prove that it is able to generate a benefit for the customers. This is especially true for businesses that offer their products or services in the area of EC and MC. Since the beginning of Internet business in the mid 1990s, models have been developed that tried to explain advantages that arose from electronic offers. An extensive overview of approaches can be found in (Pateli & Giaglis, 2002). At first, models were rather a collection of the few business models that had already proven to be able to generate a revenue stream (Fedewa, 1996; Schlachter, 1995; Timmers, 1998). Later approaches extended these collections to a comprehensive taxonomy of business models observable on the web (Rappa, 2004; Tapscott, Lowi, & Ticoll, 2000). Only Timmers (1998) provided a first classification of eleven business models along two dimensions: innovation and functional integration. Due to many different aspects that have to be considered when comparing business models, some authors introduced taxonomies with different views on Internet business. This provides an overall picture of a firm doing Internet business (Osterwalder, 2002), where the views are discussed separately (Afuah & Tucci, 2001; Bartelt & Lamersdorf, 2000; Hamel, 2000; Rayport & Jaworski, 2001; Wirtz & Kleineicken, 2000). Views are for example commerce strategy, organizational structure or business process. The two most important views that can be found in every approach are value proposition and revenue. A comparison of views proposed in different approaches can be found in (Schwickert, 2004). While the view revenue describes the rather short-term monetary aspect of a business model the value proposition characterizes the type of business that is the basis of any revenue stream. To describe this value proposition authors decomposed business models into their atomic elements (Mahadevan, 2000). These elements represent offered services or products. Models that follow this approach are for example (Afuah & Tucci, 2001) and (Wirtz & Kleineicken, 2000). Another approach that already focuses on generated value can be found in (Mahadevan, 2000). There, four so-called value streams are identified: virtual communities, reduction of transaction costs, gainful exploitation of information asymmetry, and a value added marketing process.

In this work however, we are pursuing another approach: The evaluation of real business models showed that some few business model types recur. These basic business model types have been used for building up more complex business models. They can be classified according to the type of product or service offered. A categorization based on this criterion is highly extensible and thus very generic (Turowski & Pousttchi, 2003). Unlike the classifications of electronic offers introduced previously, this approach can also be applied to mobile business models that use for example location-based services to provide a user context. In the following sections, we are describing this business model typology in detail.

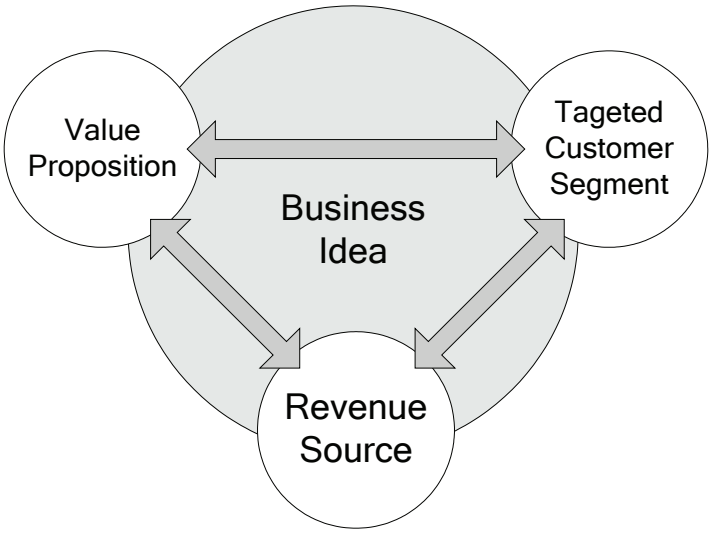
BUSINESS MODEL TYPOLOGY

Business Idea

Starting point for every value creation process is a product or business idea. An instance of a business idea is the offer to participate in auctions or conduct auctions — using any mobile device without tempo-spatial restrictions. Precondition for the economic, organisational, and technical implementation and assessment of that idea is its transparent specification. That abstracting specification of a business idea's functionality is called business model. It foremost includes an answer to the question: Why has this idea the potential to be successful? The following aspects have to be considered for that purpose:

- Value proposition (which value can be created)

Figure 1. Business idea and business model



- Targeted customer segment (which customers can and should be addressed)
- Revenue source (who, how much and in which manner will pay for the offer)

Figure 1 shows the interrelationship between those concepts. It needs to be assessed how the business idea can be implemented regarding organisational, technical, legal, and investment-related issues. Further, it has to be verified whether the combination of value proposition, targeted customer segment and revenue source that is considered optimal for the business model fits the particular company's competitive strategy. Let's assume an enterprise is pursuing a cost leader strategy using offers based on SMS, it is unclear whether the enterprise can be successful with premium-SMS.

It needs to be pointed out that different business models can exist for every single business idea. Coming back to the example of offering auctions without tempo-spatial restrictions, revenues can be generated in different ways with one business model recurring to revenues generated by advertisements and the other recurring to revenues generated by fees.

Revenue Models

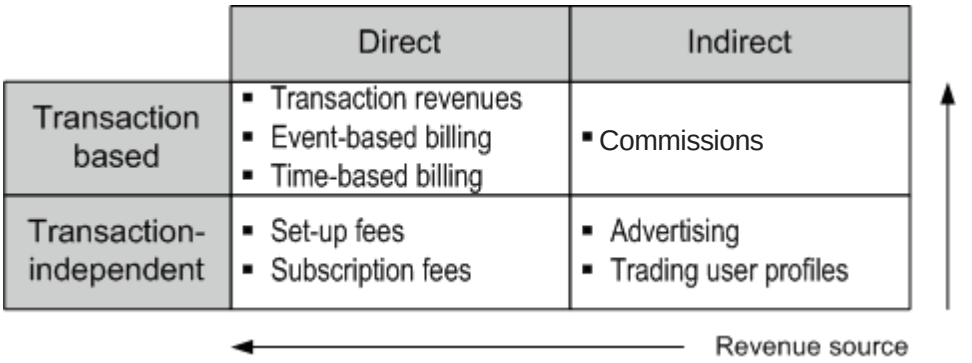
The instance introduced previously used the mode of revenue generation in order to distinguish business models. In this case, the revenue model is defined as the part of the business model describing the revenue sources, their volume and their distribution. In general, revenues can be generated by using the following revenue sources:

- Direct revenues from the user of a MC-offer
- Indirect revenues, in respect to the user of the MC-offer (i.e., revenues generated by 3rd parties); and
- Indirect revenues, in respect to the MC-offer (i.e., in the context of a non-EC offer).

Further, revenues can be distinguished according to their underlying mode in transaction-based and transaction-independent. The resulting revenue matrix is depicted in Figure 2.

Direct transaction-based revenues can include event-based billing (e.g., for file download) or time-based billing (e.g., for the participation in a blind-date game). Direct transaction-independent

Figure 2. Revenue sources in MC (based on Wirtz & Kleineicken, 2000)



revenues are generated as set-up fees, (e.g., to cover administrative costs for the first-time registration to a friend finder service) or subscription fees (e.g., for streaming audio offers).

The different revenue modes as well as the individual revenue sources are not necessarily mutually excluding. Rather, the provider is able to decide which aspects of the revenue matrix he wants to refer to. In the context of MC-offers, revenues are generated that are considered (relating to the user) indirect revenues. That refers to payments of third parties, which in turn can be transaction-based or transaction-independent. Transaction-based revenues (e.g., as commissions) accrue if, for example, restaurants or hotels pay a certain amount to the operator of mobile tourist guide for guiding a customer to their locality. Transaction-independent revenues are generated by advertisements or trading user profiles. Especially the latter revenue source should not be neglected, as the operator of a MC-offer possesses considerable possibilities for the generation of user profiles due to the inherent characteristics of context sensitivity and identifying functions (compared to the ordinary EC-vendor). Revenues that are not generated by the actual MC-offer are a further specificity of indirect revenues. This includes MC-offers pertaining to customer retention, effecting on other business activities (e.g., free SMS-information on a soccer team leading to an improvement in merchandising sales).

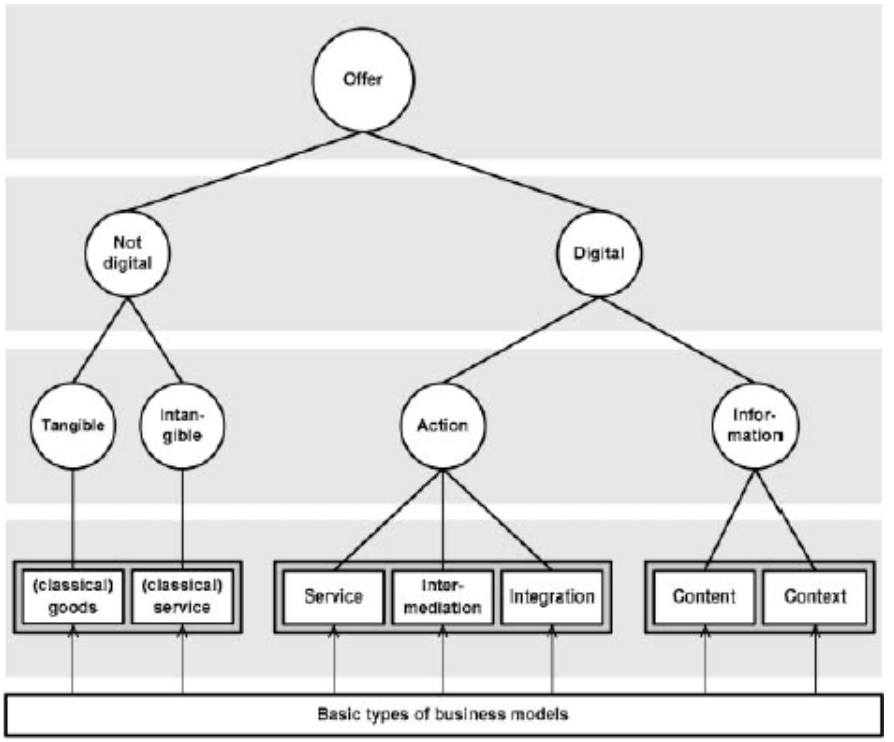
MC-Business Models

In the first step, the specificity of the value offered is evaluated. Is the service exclusively based on the exchange of digitally encoded data or is a significant not digital part existent (i.e., a good needs to be manufactured or a service is accomplished that demands some kind of manipulation conducted on a physically existing object)? *Not digital* services can be subdivided into *tangible* and *intangible* services. Whereas *tangible* services need to have a significant physical component, this classification assumes the following: The category of *intangible* services only includes services that demand manipulation conducted on a physically existing object.

Services that can be created through the exchange of digitally encoded data are subdivided into *action* and *information*. The category *information* focuses on the provision of data (e.g., multi-media contents in the area of entertainment or the supply of information). Opposed to that, the category *action* includes processing, manipulating, transforming, extracting, or arranging of data.

On the lowermost level, building blocks for business models are created through the further subdivision according to the value offered. For that purpose, a distinction is made between the concrete business models that can include one or more business model types and those business

Figure 3. Categorization of basic business model types



model types as such. These act as building blocks that can constitute concrete business models.

The business model type *classical goods* is included in all concrete business models aiming at the vending of tangible goods (e.g., CDs or flowers, i.e., goods that are manufactured as industrial products or created as agricultural produce). Those goods can include some digital components (e.g., cars, washing machines). However, decision criterion in that case is the fact that a significant part of the good is of physical nature and requires the physical transfer from one owner to the other.

Concrete business models include the business model type *classical service* if some manipulation activities have to be conducted on a physical object. That comprises e.g. vacation trips and maintenance activities.

The basic business model type *service* comprises concrete business models, if they comprise an original service that is considered by the customer as such and requires some action based on digitally encoded data as described previously, without having intermediation characteristics (c.f., basic business model type *intermediation*). Such services, e.g., route planning or mobile brokerage are discrete services and can be combined to new services through bundling. A typical offer that belongs to the business model type service is mobile banking. Further, it might be required (e.g., in order to enable mobile payment or ensure particular security goals (data confidentiality) to add further services, which require some kind of action, as described previously. As the emphasis is on the original service, these services can be considered as supporting factors. Depending on the circumstances, they might be seen as an original service. Due to that, those supporting services will not be attributed to a basic business model type. Rather, those services are assigned

to the business model type service.

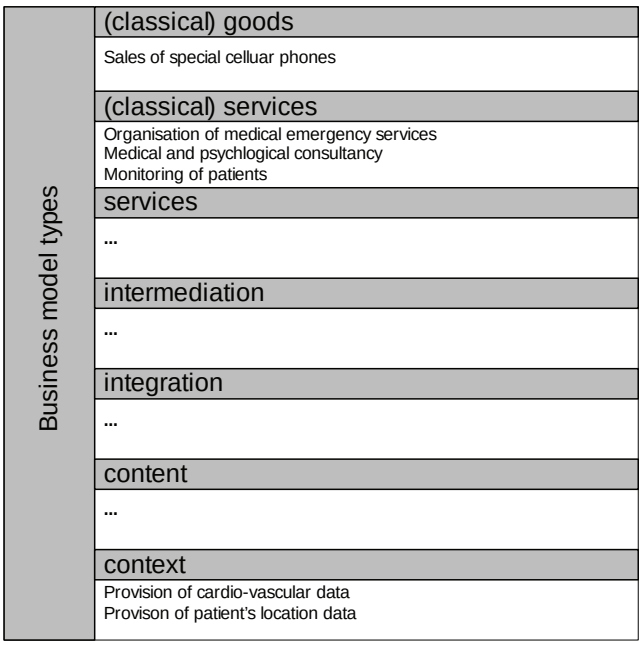
A concrete business model includes the business model type *intermediation* if it aims at the execution of classifying, systemising, searching, selecting, or interceding actions. The following offers are included:

- Typical search engines/offers (e.g., www.a1.net);
- Offers for detecting and interacting with other consumers demanding similar products;
- Offers for detecting and interacting with persons having similar interests;
- Offers for the intermediation of consumers and suppliers;
- Any kind of intermediation or brokering action, especially the execution of online auctions; and
- In general the operations of platforms (portals), which advance, simplify or enable the interaction of the aforementioned economic entities.

Taking all together, the focus is on matching of appropriate parings (i.e., the initiation of a transaction). Nevertheless, some offers provide more functionality by for example supporting the agreement process as well (e.g., the hotel finder and reservation service (wap.hotelkatalog.de)): This service lets the user search for hotels, make room reservations, and cancel reservations. All the relevant data is shown and hotel rooms can be booked, cancelled, or reserved. The user is contacted using e-mail, telephone, fax, or mail. Revenues are generated indirectly and transaction-independent, as the user agrees to obtain advertisements from third parties.

The basic business model type *integration* comprises concrete business models aiming at the combination of (original) services in order to create a bundle of services. The individual services might be a product of concrete business models that in turn can be combined to create new offers. Further, the fact that services have been combined is not necessarily transparent for the consumer. This can even lead to user individual

Figure 4. Classification of Vitaphone's business model



offers where the user does not even know about the combination of different offers. For example, an offer could be an insurance bundle specifically adjusted to a customer's needs. The individual products may come from different insurance companies. On the other hand, it is possible to present this combination to the consumer as the result of a customization process (custom-made service bundle).

The basic business model type *content* can be identified in every concrete business model that generates and offers digitally encoded multi-media content in the areas of entertainment, education, arts, culture sport etc. Additionally, this type comprises games. Wetter-Online (pda.wetteronline.de) can be considered a typical example for that business model type. The user can access free weather information using a PDA. The information offered includes forecasts, actual weather data, and holiday weather. The PDA-version of this service generates no revenues, as it is used as promotion for a similar EC-offer, which in turn is ad sponsored.

A concrete business model comprises the basic business model type *context* if information describing the context (i.e., situation, position, environments, needs, requirements etc.) of a user is utilised or provided. For example, every business model building on location-based services comprises or utilises typical services of the basic business model type context. This is also termed context-sensitivity. A multiplicity of further applications is realised in connection with the utilisation of sensor technology integrated in or directly connected to the mobile device. An instance is the offer of Vitaphone (www.vitaphone.de). It makes it possible to permanently monitor the cardiovascular system of endangered patients. In case of an emergency, prompt assistance can be provided. Using a specially developed mobile phone, biological signals, biochemical parameters, and the users' position are transmitted to the Vitaphone service centre. Additionally to the aforementioned sensors, the mobile phone has GPS functionality and a special emergency button to establish quick contact with the service centre.

Figure 4 depicts the classification of that business model using the systematics introduced previously. It shows that vita phone's business model uses mainly the building blocks from the area of *classical service*. Those services are supplemented with additional building blocks from the area of *context*. This leads to the weakening of the essential requirement — physical proximity of patient and medical practioner — at least what the medical monitoring is concerned. This creates several added values for the patient, which will lead to the willingness to accept that offer.

Analysing the offer of Vitaphone in more detail leads to the conclusion that the current offer is only a first step. The offer results indeed in increased freedom of movement, but requires active participation of the patient. He has to operate the monitoring process and actively transmit the generated data to the service centre. To round of the analysis of Vitaphone's business model, the revenue model is presented in Figure 5.

Non MC-relevant revues are generated by selling special cellular phones. Further, direct MC revenues are generated by subscription fees (with or without the utilisation of the service centre) and transmission fees (for data generated and telephone calls using the emergency button).

CONCLUSION

This chapter presents an approach to classify mobile business models by introducing a generic mobile business model typology. The aim was to create a typology that is as generic as possible, in order to be robust and applicable for business models that do not exist today. The specific characteristics of MC make it appropriate to classify the business models according to the mode of the service offered. Doing so, building blocks in the form of business model types can be identified. Those business model types then can be

Figure 5. Vitaphone's revenue model

MC-Business			Non-MC-Business
	Direct	Indirect	
Transaction based	▪ Communication with the service centre	...	Sales of special celluar phones
Transaction-independent	▪ Subscription fee	...	

combined to create concrete business model. The resulting tree of building blocks for MC business models differentiates digital and not digital services. Not digital services can be subdivided into the business model types classical goods for tangible services and classical service for intangible services. Digital services are divided into the category action with the business model types service, intermediation, integration and the category information with the business model types content and context.

Although the typology is generic and is based on the analysis of a very large number of actual business models, further research is necessary to validate this claim for new business models from time to time.

INTRODUCTION

Open-source software (OSS) is software that can be used freely in the public domain but is often copyrighted by the original authors under an open-source license such as the GNU General Public License (GPL). Given its free nature, one might believe that OSS is inherently inferior to proprietary software, yet this often is not the case. Many OSS applications are superior or on par with their proprietary competitors (e.g., MySQL, Apache Server, Linux, and Star Office). OSS is a potentially disruptive technology (Christensen, 1997) because it is often cheaper, more reliable, simpler, and more convenient than proprietary software.

Because OSS can be of high quality and capable of performing mission-critical tasks, it is becoming common in industry; the majority of Web sites, for example, use Apache as the Web

server. The deployment of OSS is proving to be a productive way to counter the licensing fees charged by proprietary software companies. An organized approach to distributing cost-effective OSS products is intensifying as companies such as RedHat and IBM co-brand OSS products to establish market presence.

From a business perspective, the entire OSS movement has been strategically anti-intuitive because it is based on software developers freely sharing source code—an act that flies in the face of traditional proprietary models. This movement raises two questions this article aims to address: (1) why would individuals write software and share it freely? and (2) how can software firms make money from OSS? Before fully addressing these questions, this article examines the historical development of OSS.

OSS HISTORY

A strategic irony of the software industry is that its foundation rests primarily on OSS principles. Software development in the 1960s and 1970s was steered primarily by government and academia. Software developers working in the field at the time considered it a normal part of their research culture to exchange, modify, and build on one another's software (Von Krogh, 2003). Richard Stallman, a professor and programmer at MIT, was a strong advocate and contributor to this culture of open, collaborative software development. Despite Professor Stallman's influence, MIT eventually stopped exchanging sourcecode with other universities to increase its research funding through proprietary software licensing. Offended by MIT's decision to limit code sharing, Professor Stallman founded the Free Software Foundation in 1985 and developed the General Public License (GPL) to preserve free code sharing (Bretthauer, 2002).

In the formative years of the software industry, Stallman's free software movement grew slowly; in the early 1990s, however, the concept of code sharing grew more rapidly for a couple of reasons. First, "free software" was renamed "OSS," a name that spread rapidly throughout the code-sharing community (Fitzgerald & Feller, 2001). Second, the OSS movement received a boost from the advent of the World Wide Web (WWW). The Web provided an opportunity for Internet users to quickly and conveniently share their code.

WHY DEVELOPERS WRITE OSS

The majority of OSS software developers fall into one of the following three categories: freelancers, software enthusiasts, or professionals. Freelancers

Table 1. Developer motivations

Enthusiast	Freelancer	Professional
• Learn	•Challenge of developing code	• Programming income
•Earn respect	•Receive future job opportunities	•Customize OSS

Intrinsic → Extrinsic

enjoy the challenges associated with developing OSS and providing services to the OSS community to further their own careers. When freelancers create modules of code, they often include their contact information inside the modules (Lerner & Tirole, 2002). This allows businesses to contact the developers to request their future services.

Software enthusiasts are people who contribute to OSS simply out of the joy and challenge of doing so, with little regard for professional advancement. Enthusiasts are often university students who want to participate in the development of free software and who receive personal gratification from participating in real-world OSS development projects and gaining the respect of the OSS community.

Even though OSS is "free" software, many companies hire professional developers to work on improving OSS code. RedHat, a Linux support company, hires developers to fix bugs in OSS code and to create new applications (Lerner & Tirole, 2002). Other companies hire OSS developers because their systems run OSS applications and they need developers to customize the code for specific business purposes. Table 1 summarizes the different motivations for joining OSS projects and shows them on a spectrum of intrinsic and extrinsic motivations.

SOFTWARE DEVELOPMENT ECONOMICS

Proprietary Software

The strategic motivation behind the creation of proprietary software is to set up high switching costs for consumers. For such companies their developers' resulting source code becomes the company's intellectual property and an unshared key company asset. Once customers purchase proprietary software, they must pay for updates continually to keep the software current, and often to receive full customer support (Delong & Froomkin, 2000). Most customers will pay these fees because of the lock in that occurs from the often costly prohibitive tradeoff of implementing a completely new system.

Microsoft is an example of a company that has succeeded in proprietary software, largely because they have a focused strategy of selling complementary products and services to their installed base of Windows users (Shapiro & Varian, 1998): Offering complementary goods that run on Windows (e.g., Office) increases profitability and successfully enhances the buyer relationship while encouraging customer entrenchment.

Proprietary software development is rigidly structured. Development begins with an end product in mind, and the new product often integrates with other products the company is currently selling. Project leaders create development plans, set deadlines, and coordinate teams to develop modules of the new software product. Successful proprietary software companies are also able to develop new technologies in exceptionally short time frames and to place their products in the market faster than their competitors. Products that meet the strict demands of end users succeed and increase customer satisfaction.

The downside of proprietary software development is that it comes at a tremendous internal cost (Lederer & Prasad, 1993); meanwhile, the industry is experiencing increasing pressures to decrease costs. Companies must invest heavily in research and development (R&D), human capital, information technology, marketing, brand development, and physical manufacturing of the products. They must continually innovate and develop updated versions of existing products, or create entirely new products. To compensate for these costs, proprietary software companies have high-priced products. Some software costs are so high that many businesses question whether the software is worth it.

OSS

The economics of OSS differ significantly in that OSS is developed in a loose marketplace structure. The development process begins when a developer presents an idea or identifies a need for an application with specific functionality (Johnson, 2002). OSS software development typically has a central person or body that selects a subset of developed code for an "official" release and makes it widely available for distribution. OSS is built by potentially large numbers of volunteers in combination with for-profit participants (Von Krogh, 2003). Often no system-level design or even detailed design exists. Developers work in arbitrary locations, rarely or never meet face to face, and often coordinate their activity through e-mail and bulletin boards. As participants make changes to the original application, the central person or body leading the development selects code changes, incorporates them into the application, and officially releases the next version of the application. Table 2 compares OSS to proprietary development.

OSS BUSINESS MODELS

A business model is a method whereby a firm builds and uses resources to provide a value-added proposition to potential customers (Afuah & Tucci, 2000). OSS business models are based on providing varied services that cater to cost-sensitive market segments and provide value to the end user by keeping the total cost of ownership as low as possible (Hecker, 1999). OSS-based companies must provide value-added services that are in demand, and they must provide these services at cost-sensitive levels. OSS is a strategic threat to proprietary software, because one of the most effective ways to compete in lock-in markets is to "change the game" by expanding the set of complementary products beyond those offered by rivals (Shapiro & Varian, 1998). OSS proponents are trying to "change the game" with new applications of the following business models (Castelluccio, 2000): support sellers, loss leaders, code developers, accessorizers, certifiers, and tracking service providers.

Table 2. OSS development vs. proprietary development

OSS	Proprietary Software
Similarities	
Building brand name and reputation increases software use	
Revenue is generated from supporting software, creating new applications for software, and certifying software users	
Differences	
Code developed outside of company for free	Developers are paid to program code
Source code is open for public use.	Source code is kept in company
People use program without paying any license fees.	Users pay license fees to use the software
Updates are free and users are allowed flexibility in using them	People are locked in using specific software and have to pay for updates
Code is developed for little internal cost	Code is costly to create internally

Support Sellers

Support sellers provide OSS to customers for free, except for a nominal packaging and shipping fee, and instead charge for training and consulting services. They also maintain the distribution channel and branding of a given OSS package. They provide value by helping corporations and individuals install, use, and maintain OSS applications. An example of a support seller is RedHat, which provides reliable Linux solutions.

To offer such services, support sellers must anticipate and provide services that will meet the needs of businesses using OSS. To offer reliable and useful consulting services, support sellers must invest heavily in understanding the currently available OSS packages and developing models to predict how these OSS applications will evolve in the future (Krishnamurthy, 2003).

This model has strengths in meeting the needs for outsourcing required IT services, which is the current market trend (Lung Hui & Yan Tam, 2002). OSS provides companies an opportunity to reduce licensing costs by allowing companies to outsource the required IT support to support sellers. Likewise, the marketplace structure of OSS development adds significant uncertainty to the future of OSS applications. Risk-adverse companies often do not want to invest in specialized human capital, and support sellers help mitigate these risks.

One drawback of this model is that consulting companies often fall prey to economic downturns, during which potential clients reduce outsourcing to consultants. This cycle is compounded for the software industry, since a poor economy results in cost cutting and an eventual reduction in IT spending.

Loss leaders

Loss-leader companies write and license proprietary software that can run on OSS platforms (Castelluccio, 2000). An example of a loss leader is Netscape, which gives away its basic Web-browser software but then provides proprietary software or hardware to ensure compatibility and allow expanded functionality. The loss-leader business model adds value by providing applications to companies that have partially integrated OSS with their systems (Hecker, 1999). Companies often need specific business applications that are unavailable in the OSS community, or they desire proprietary applications but wish to avoid high platform-licensing costs.

To leverage the integration of OSS with proprietary software, loss leaders need to assemble a team of highly skilled developers, create an IT infrastructure, and develop licensable applications. The major costs of this business model arise from payroll expenses for a development team, R&D costs, marketing, and, to a lesser extent, patenting and manufacturing.

This model's strength is that it provides a solution for the lack of business applications circulating in the OSS community. The loss leader model fills the gap between simpler available OSS applications, such as word processors, and more complex applications that are unavailable in the OSS community.

A weakness of this model is the risk of disintermediation. As time passes and OSS coding continues to grow and expand, more robust and complex applications will be developed. However, the developers of these applications will have to cope with the speed and efficiency of proprietary software development.

Code Developers

The code development model addresses some of the limitations of the loss-leader model. Code development companies generate service revenue through on-demand development of OSS. If a firm cannot find an OSS package that meets its needs for an inventory management system, for example, the firm could contract with a code development company to the basic application (Johnson, 2002).

The code development company could then distribute this application to the OSS community and act as the development project's leader. The code development company would track the changes made to the basic source code by the OSS community and integrate those changes into its product. The company would periodically send its customers product updates based on changes accepted from the OSS community.

The necessary assets and associated costs required by this model are similar to those in the proprietary software model, including a team of programmers, IT infrastructure, and marketing. However, the code developer needs to develop only a basic application. Once the basic software is developed, the OSS community provides further add-ons and new features (Johnson, 2002), which decrease the R&D costs for the company acting as project leader. Yet the code development team needs to have the necessary IT infrastructure to lead the OSS community in the application's evolution, incorporate new code, and resubmit new versions to its customers.

This model's strength is its longevity. The code development model overcomes the risk of disintermediation by basing its revenue generation on initiating OSS applications and maintaining leadership over their evolution; it does not focus on privatizing the development and licensing of applications.

This model's weakness is the risk of creating an application of limited interest to the OSS community. A possible solution to this problem would be an offer from the company leading the development process to reward freelance developers for exceptional additions to the application's original code.

Accessorizers

Accessorizers companies add value by selling products related to OSS. Accessorizers provide a variety of different value-added services, from installing Linux OS on their clients' hardware to writing manuals and tutorials (Hecker, 1999; Krishnamurthy, 2003). For example, O'Reilly & Associates, Inc. writes manuals for OSS and produces downloadable copies of Perl, a programming language.

One strength of this model is that it provides the new manuals and tutorials that the constantly changing nature of the OSS market requires. Another strength is its self-perpetuating nature: as more manuals and tutorials are produced, more people will write and use OSS applications, increasing the need for more manuals and tutorials.

This models' weakness is the difficulty of staying current with the many trends with the OSS community. This difficulty creates the risk of investing in the wrong products or producing too much inventory that is quickly outdated.

Certifiers

Certifiers establish methods to train and certify students or professionals in an application. Certificate companies like CompTIA generate revenue through training programs, course materials, examination fees, and certification fees. These programs provide value to the individuals enrolled in the certification programs and businesses looking for specific skills (Krishnamurthy, 2003). Certification helps the OSS industry by creating benchmarks, expectations, and standards employers can use to evaluate and hire employees based on specific skill sets.

Certification has long-term profit potential since most certification programs require recertification every few years due to continuing education requirements. Businesses value certification programs because they are a cost-effective way to train employees on new technologies. Certifiers, who achieve first-mover advantage, become trendsetters for the entire industry, increasing barriers to entry into the certification arena.

One downside of this model is the significant startup costs. Certifiers need to find qualified in-

dividuals to create manuals, teach seminars, and write tests. Certifiers must also survey businesses to discern which parts of specific applications are most important, and which areas need the greatest focus during training. Certifiers also need to gain substantial credibility through marketing and critical mass or their tests have little value. Increasing company name recognition and building a reputation in the certification arena can be an expensive and long process.

This model also faces the threat of disintermediation. Historically, certification programs have evolved into not-for-profit organizations, such as the AICPA in accounting, or the ISO 9000 certification in operations. The threat of obsolescence is another major weakness. In the 1970s, FORTRAN or COBOL certification may have been important (Castelluccio, 2000), but they have since become obsolete. Certifiers specializing in certain applications must be constantly aware of the OSS innovation frontier and adjust their certification options appropriately.

Tracking Service Providers

The tracking-services business model generates revenue through the sale of services dedicated to tracking and updating OSS applications. For example, many companies have embraced Linux to cut costs; however, many of these same companies have found it difficult to maintain and upgrade Linux because of their lack of knowledge and resources. Tracking-services companies, like Sourceforge.net and FreshMeat.net, sell services to track recent additions, define source code alternatives, and facilitate easy transition of code to their customers' systems.

A strength of this model is its ability to keep costs low by automating the majority of the work involved in tracking while still charging substantial subscription and download fees. However, these services must have Web-based interfaces with user-friendly download options, and they also must develop human and technological capabilities that find recent updates and distinguish between available alternatives.

A weakness of this model is low barriers to entry. This information-services model can be replicated with a simple Web interface and by spending time on OSS discussion boards and postings, creating the possibility of such services becoming commoditized. Table 3 summarizes some of the differences between the OSS business models.

CONCLUSION

The market battle between OSS and proprietary software has just begun. This battle could be termed a battle of complementary goods and pricing. For example, the strategies between Microsoft and RedHat are similar in that they both need a large, established user base that is locked in and has access to a large array of complementary goods and services. The key differences in their strategies are in their software development process, software distribution, intellectual property ownership, and pricing of core products and software. It will be increasingly important for OSS companies to track the competitive response of proprietary companies in combating the increasing presence of OSS.

Moreover, the OSS movement has begun to make inroads into the governments in China, Brazil, Australia, India, and Europe. As whole governments adopt OSS the balance of power can shift away from proprietary providers. This also provides the opportunity to develop a sustainable business model that caters only to the government sector. Similarly, formulating business models for corporations and educational institutions may be another fruitful opportunity.

The recent government regulations associated with the Sarbanes-Oxley Act and other financial-reporting legislation are important trends. These regulations require significant research in the area of internal control reporting on OSS applications.

Table 3. OSS models

Business Model	Assets	Costs	Revenue Model
Support Sellers	Human capital, supporting infrastructure, contracts	Payroll, IT, marketing and brand development	Training, consulting
Loss Leaders	Human capital, supporting infrastructure, software	Payroll, IT cost, marketing and brand development, R&D, software manufacturing	Licenses
Accessorizers	Human capital, supporting infrastructure	Payroll, printing material machines, training, software	Book Sales
Code developers	Human capital, software - technology tracking, database	Payroll, IT, marketing (Corporations), marketing (Freelancers)	Corporations that pay for service
Certifiers	Human capital, IT, Certification program	Certification program development, payroll	Tests, certificates
Tracking-service providers	Human capital, Software-technology tracking, Databases	Payroll, IT, marketing (Corporations)	Corporations that pay for service

It is likely the collaborative and less proprietary nature of OSS could help with this reporting. If this reporting can be done with more assurance than provided by proprietary applications, OSS providers can gain further advantage.

Chapter 6.8
Learning through Business Games

Luigi Proserpio
Bocconi University, Italy

Massimo Magni
Bocconi University, Italy

BUSINESS GAMES: A NEW LEARNING TOOL

Managerial business games, defined as interactive computer-based simulations for managerial education, can be considered as a relatively new tool for adults' learning. If compared with paper-based case histories, they could be less consolidated in terms of design methodologies, usage suggestions, and results measurement.

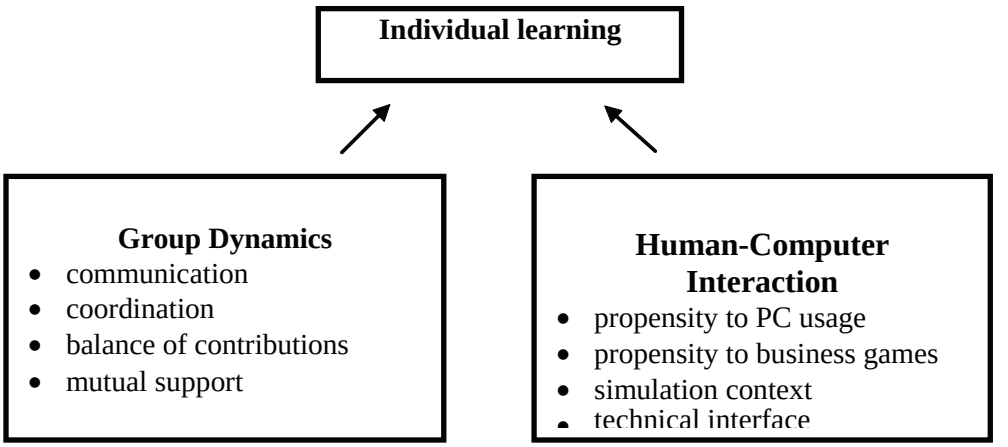
Due to the growing interest around Virtual Learning Environment (VLE), we are facing a positive trend in the adoption of business games for undergraduate and graduate education. This process can be traced back to two main factors. On the one hand, there is an increasing request for non-traditional education, side by side with an educational model based on class teaching (Alavi & Leidner, 2002). On the other hand, the rapid development of information technologies has made available specific technologies built around learning development needs (Webster & Hackley, 1997). Despite the increased interest generated by business games, many calls have still to be addressed on the design and utilization side. This contribution describes two fundamental aspects related with business games in graduate and undergraduate education: group dynamics (as current business games are almost in all instances played in groups) and human-computer interaction.

Figure 1 represents the variables that could influence individual learning in a business game context.

THE INFLUENCE OF GROUP DYNAMICS

It is widely accepted that a positive climate among subjects is fundamental to enhance the productivity of the learning process (Alavi, Wheeler,

Figure 1. Variables influencing individual learning in a business game setting



& Valacich, 1995). This is why group dynamics are believed to have a strong impact on learning within a team based context. A clear explanation of group dynamics impact on performance and learning is well developed in the teamwork quality construct (TWQ) (Hoegl & Gemuenden, 2001). Group relational dynamics are even more important when the group is asked to solve tasks requiring information exchange and social interaction (Gladstein, 1984), such as a business game. In fact, the impact of social relations is deeper when the task is complex and characterized by sequential or reciprocal interdependencies among members.

With reference to TWQ, it is possible to point out different group dynamics variables with a strong influence on individual learning in a business game environment: communication, coordination, balance of contributions, and mutual support. Instructors and business games designers should carefully consider the following variables, in order to maximize learning outcomes.

Hereafter, focusing on a business game setting, we will discuss each of these concepts and their relative impact on individual learning.

Communication

In order to develop effective group decision processes, information exchange among members should also be effective. In fact, communication is the way by which members exchange information (Pinto & Pinto, 1990), and smooth group functioning depends on communication easiness and efficacy among members (Shaw, 1981).

Moreover, individuals should be granted an environment where communication is open. A lack of openness should negatively influence the integration of knowledge and group members' experiences (Gladstein, 1984; Pinto & Pinto, 1990). These statements are confirmed by several empirical studies, showing direct and strong correlation between communication and group performance (Griffin & Hauser, 1992). According to Kolb's experiential learning theory, in a learning setting based on experiential methods (i.e., business game), it is important to provide the classroom with an in-depth debriefing in order to better understand the link between the simulation and the related theoretical assumption.

For these reason, groups with good communication dynamics tend to adopt a more participative behavior during the debriefing session, with higher quality observations. As a consequence, there is

a process improvement in the acquisition, generation, analysis and elaboration of information among members (Proserpio & Magni, 2004).

Balance of Contributions

It can be defined as the level of participation of each member in the group decision process. Each member, during the decision process, brings to the group a set of knowledge and experiences that allows the group to develop a cognitive advantage over individual decision process. Thus, it is necessary that each member brings his/her contributions to the group (Seers, Petty, & Cashman, 1995) in order to improve performance, learning and satisfaction of team members (Seers, 1989). A business game setting requires a good planning and implementation of strategies in order to better face the action-reaction process with the computer. For this reason, a balanced contribution among members favors the cross fertilization and the development of effective game strategies.

Coordination

A group could be seen as a complex entity integrating the various competencies required to solve a complex task. For this reason, a good balance of members' contribution is a necessary condition, although not sufficient. The expression of the group cognitive advantage is strictly tied to the harmony and synchronicity of members' contribution, that is, the degree according to which they coordinate their individual activities (Tannenbaum, Beard, & Salas, 1992).

As for communication, individuals belonging to groups with a better coordination level show better interventions in the debriefing phases. They also offer good hints to deepen the topics included in the simulation, playing as an intellectual stimulus for each other.

Mutual Support

It can be defined as the emergence of cooperative and mutually supporting behaviors, which lead to better team effectiveness (Tjosvold, 1984). In contrast, it is important to underline that competitive behaviors within a team determine distrust and frustration.

Mutual support among participants in a business game environment could be seen as an interference between the single user and the simulation: every discussion among users on simulation interpretation distracts participants from the ongoing simulation. This is why the emergence of cooperative behaviors does not univocally lead to more effective learning processes. These relations lower users' concentration and result in obstacles in the goal achievement path. Moreover, during a business game, users play in a time pressure setting, which brings to a drop in the effectiveness of the decision process. All these issues, according to group effectiveness theories, help to understand how mutual support in a computer simulation environment could show a controversial impact on individual learning (Proserpio & Magni, 2004).

THE INFLUENCE OF HUMAN-COMPUTER INTERACTION

Business games are often described as proficient learning tools. Despite the potentiality, as stressed by Eggleston and Janson (1997), there is the need for an in-depth analysis of the relationship between user and computer. On the design side, *naïve* business games (not designed by professionals) can hinder the global performance of a simulation and bring to negative effects on the learning side. For these reason, technological facets are considered as a fundamental issue for a proficient relationship between user and computer in order to improve learning process effectiveness (Alavi & Leidner, 2002; Leidner & Jarvenpaa, 1995).

Propensity to PC Usage

Attitude toward PC usage can be defined as the user's overall affective reaction when using a PC (Venkatesh et al., 2003). Propensity to PC usage can be traced back to the concepts of pleasure, joy, interest associated with technology usage (Compeau, Higgins, & Huff, 1999). It is consistent to think that users' attitude towards computer use could influence their use involvement, increasing or decreasing the impact of simulation on learning process.

From another standpoint, more related to HCI theories, computer attitude is tied to the simulation easiness of use. It is possible to argue that a simple simulation does not require strong computer attitude to enhance the leaning process. On the contrary, a complex simulation could worsen individual learning, because the cognitive effort of the participant can be deviated from the underlying theories to a cumbersome interface.

Propensity to Business Game Usage

This construct can be defined as the cognitive and affective elements that bring the user to assume positive/negative behaviors toward a business game. In fact, in these situations, users can develop feelings of joy, elation, pleasure, depression, or displeasure, which have an impact on the effectiveness of their learning process (Taylor & Todd 1995). Consistently with Kolb's theory (Kolb, 1984) on individual different learning styles, propensity to simulations could represent a very powerful element to explain individual learning.

Simulation Context

The simulation context can be traced back to the role assumed by individuals during the simulation. In particular, it is referred to the role of participants, teacher and their relationship. Theory and practice point out that business games have to be self-explaining. In other words, the intervention of other users or the explanations of a teacher to clarify simulation dynamics have to be limited. Otherwise, the user's effort to understand the technical and interface features of the simulation could have a negative influence on learning objectives (Whicker & Sigelman, 1991). Comparing this situation with a traditional paper-based case study, it is possible to argue that good instructions and quick suggestions during a paper-based case history analysis can help in generating users' commitment and learning. On the contrary, in a business game setting, a self explanatory simulation could bring users to consider the intervention of the teacher as an interruption rather than a suggestion. Thus, simulations have often an impact on the learning process through the reception step (Alavi & Leidner, 2002), meaning that teacher's or other members' intervention hinder participants to understand incoming information.

Technical Interface

Technical interface can be defined as the way in which information is presented on the screen (Lindgaard, 1994). In a business game, the interface concept is also related to the interactivity facet (Webster & Hackley, 1997). Several studies have pointed out the influence of technical interface on user performance and learning (Jarvenpaa, 1989; Todd & Benbasat, 1991). During the business game design, it is important to pay attention to the technical interface. It is essential that the interface captures user attention, thereby increasing the level of participation and involvement. According to the above mentioned studies, it is possible to argue that an attractive interface could represent one of the main variables that influence the learning process in a business game setting.

Face Validity

Face validity defines the coherence of simulation behaviors in relation with the user's expectancies

on perceived realism. It is also possible to point out that the perceived soundness of the simulation is a primary concept concerning the users' learning (Whicker & Sigelman, 1991). The simulation cannot react randomly to the user's stimulus, but it should recreate a certain logic path which starts from player action and finishes with the simulation reaction. It is consistent with HCI and learning theories, to argue that an effective business game has to be designed to allow users to recognize a strong coherence among simulation reactions, their actions, and their behavior expectancies.

ADDITIONAL ISSUES TO DESIGN A BUSINESS GAME

The main aspect that has to be considered when designing a business game is the ability of the simulation to create a safe test bed to learn management practices and concepts. It is fundamental that users are allowed to experiment behaviors related to theoretical concepts without any real risk. This issue, together with aspects of fun and the creation of a group collaboration context, could be useful to significantly improve the learning level.

Thus, a good simulation is based on homomorphic assumptions. Starting from the existence of a reality with *n* characteristics, homomorphism is the ability to choose *m* (with $n>m$) characteristics of this reality in order to reduce its complexity without losing too much relevant information. For example, in a F1 simulation game, racing cars can have a different behavior on a wet or dry circuit, but they cannot have a different behavior among wet, very wet, or almost wet.

In order to minimize the negative impact on learning processes, it is important that characteristics not included in the simulation should not impact too much on the simulation realism.

CONCLUSION

Several studies have shown the importance of involvement and participation in the fields of standard face-to-face education and in distance learning environments (Webster & Hackley, 1997). This research note extends the validity of previous statements to the business game field.

The discussion above allows us to point out a relevant impact on learning of two types of variables, while using a business game: group dynamics and human-computer interaction.

From previous researches, it is possible to argue that the "game" dimension captures a strong part of participants' cognitive energies (Proserpio & Magni, 2004). The simulation should be designed in a fashion as interactive as possible. Moreover, instructors should take into account that their role is to facilitate the simulation flow, leaving the game responsibility to transmit experiences on theories and their effects.

This is possible if the simulation is easy enough to understand and use. In this case, despite the fact that the simulation is computer based, there is not the emergence of a strong need for computer proficiency. This conclusion is consistent with other researches which showed the impact of the easiness of use on individual performance and learning (Delone & McLean, 1992).

The relationship between user and machine is mediated by the interface designed for the simulation, which represents a very powerful variable to explain and favor the learning process with these high involvement learning tools.

Computer simulations seem to have their major strength in the computer interaction, which ought to be the main focus in the design phase of the game. Interaction among groups' members is still important, but less relevant than the interface on individual learning.

KEY TERMS

Business Games: Computer-based simulations designed to learn business-related concepts.

Experiential Learning: A learning model "which begins with the experience followed by reflection, discussion, analysis and evaluation of the experience" (Wight, 1970, p. 234-282).

HCI (Human-Computer Interaction): A scientific field concerning design, evaluation, and implementation of interactive computing systems for human usage.

Interface: An interface is a set of commands or menus through which a user communicates with a software program.

TWQ (Teamwork Quality): A comprehensive concept of the quality of interactions in teams. It represents how well team members collaborate or interact.

Usability: The ease with which a user can learn to operate, prepare inputs for, and interpret outputs of a system or component (Institute of Electrical and Electronics Engineers).

VLE (Virtual Learning Environments): Computer-based environments for learning purposes.

Chapter 6.9
Internet Privacy from the Individual and Business Perspectives

Tziporah Stern
Baruch College, CUNY, USA

INTRODUCTION: PRIVACY

People have always been concerned about protecting personal information and their right to privacy. It is an age-old concern that is not unique to the Internet. People are concerned with protecting their privacy in various environments, including healthcare, the workplace and e-commerce. However, advances in technology, the Internet, and community networking are bringing this issue to the forefront. With computerized personal data files:

a. Retrieval of specific records is more rapid;
b. Personal information can be integrated into a number of different data files; and
c. Copying, transporting, collecting, storing, and processing large amounts of information are easier.

In addition, new techniques (i.e., data mining) are being created to extract information from large databases and to analyze it from different perspectives to find patterns in data. This process creates new information from data that may have been meaningless, but in its new form may violate a person's right to privacy. Now, with the World Wide Web, the abundance of information available on the Internet, the many directories of information easily accessible, the ease of collecting and storing data, and the ease of conducting a search using a search engine, there are new causes for worry (Strauss & Rogerson, 2002). This article outlines the specific concerns of individuals, businesses, and those resulting from their interaction with each other; it also reviews some proposed solutions to the privacy issue.

CONTROL: PRIVACY FROM THE INDIVIDUAL'S PERSPECTIVE

The privacy issue is of concern to many types of people and individuals from different backgrounds. Gender, age, race, income, geographical location, occupation, and education level all affect people's views about privacy. In addition, culture (Milberg et al., 2000; Smith, 2001) and the amount of Web experience accumulated by an individual is likely to influence the nature of the information considered private (Hoffman et al., 1999; Miyazaki & Fernendez, 2001). Table 1 summarizes the kinds of information people would typically consider private.

When interacting with a Web site, individuals as consumers are now more wary about protecting their data. About three-quarters of consumers who are not generally concerned about privacy fear intrusions on the Internet (FTC, 2000). This is due to the digitalization of personal information, which makes it easier for unauthorized people to access and misuse it (see Table 2 for a list of concerns regarding the uses of data). For example, many databases use Social Security numbers as identifiers. With this information and the use of the Internet, personal records in every state's municipal database can be accessed (Berghel, 2000).

Table 1. Private information

Information
▪ Address
▪ Credit card numbers
▪ Date of birth
▪ Demographic information
▪ E-mail
▪ Healthcare information and medical records
▪ Name
▪ Phone number
▪ Real-time discussion
▪ Social Security number
▪ Usage tracking/click streams (cookies)

There also are many issues regarding policies and security controls. Individuals are concerned about breaches of security and a lack of internal controls (Hoffman, 2003). However, surprisingly, about one-third of Web sites do not post either a privacy policy or an information practice statement (Culnan, 1999), and only about 10% address all five areas of the Fair Information Practices (FIP), U.S. guidelines to protect computerized information (see FIP in Terms section) (Culnan, 1999; Federal Trade Commission, 2000). Additionally, there is a mismatch between policies and practices (Smith, 2001); this means that a company may publicize fair information policies but in practice does not follow its own guidelines.

Furthermore, as a result of the data mining technology, computer merging and computer matching have become a new privacy concern. One reason is because individuals may have authorized data for one purpose but not for another, and through data mining techniques, this information is extracted for further use and analysis. For example, a consumer's information may have been split up among many different databases. However, with sophisticated computer programs, this information is extracted and used to create a new database that contains a combination of all the aggregate information. Some of these data mining techniques may not be for the benefit of the consumer. It may allow the firms to engage in price and market discrimination by using consumers' private information against them (Danna & Gandy, 2002).

Some additional concerns are whether the Web site is run by a trusted organization, whether individuals can find out what information is stored about them, and whether their name will be removed from a mailing list, if requested. Consumers also want to know who has access to the data and if the data will be sold to or used by third parties. They want to know the kind of information collected and the purpose for which it is collected (Cranor et al., 1999; Hoffman, 2003). In addition, consumers want to feel in control

Table 2. Individual's concerns

Concerns
▪ Access
▪ Analyzing
▪ Collection
▪ Combining data
▪ Contents of the consumer's data storage device
▪ Creating marketing profiles of consumers
▪ Cross matching
▪ Distributing and sharing
▪ Errors in data
▪ Identity theft
▪ Reduced judgment in decision making
▪ Secondary use of data
▪ Selling data (government)
▪ Spam
▪ Storing
▪ Use
▪ Video surveillance on the Internet
▪ Web bugs

of their personal information (Hoffman, 2003; Olivero & Lunt, 2004). According to a Harris Poll (2003), 69% of consumers feel they have lost control of their personal information.

TRUST: PRIVACY FROM THE BUSINESS PERSPECTIVE

Privacy also is important to businesses. A business collects information about its customers for many reasons: to serve them more successfully, to build a long-term relationship with them, and to personalize services. To build a successful relationship, businesses must address their customers' privacy concerns (Resnick & Montania, 2003) so that their customers will trust them. They must also protect all information they have access to, since this is what consumers expect of them (Hoffman et al., 1999). Furthermore, they must be aware of the fact that some information is more sensitive (Cranor et al., 1999), such as Social Security numbers (Berghel, 2000). This trust is the key to building a valuable relationship with customers (Hoffman et al., 1999; Liu et al. 2004).

One of the many ways a business can gain consumer confidence is by establishing a privacy policy, which may help consumers trust it and lead them to return to the Web site to make more purchases (Liu et al., 2004). When a business is trusted, consumers' privacy concerns may be suppressed, and they may disclose more information (Xu et al., 2003). Privacy protection thus may be even more important than Web site design and content (Ranganathan & Ganapathy, 2002). Also, if an organization is open and honest with consumers, the latter can make a more informed decision as to whether or not to disclose information (Olivero & Lunt, 2004).

INDIVIDUAL VS. BUSINESS = PRIVACY VS. PERSONALIZATION

In matters of information, there are some areas of conflict between businesses and consumers. First, when a consumer and an organization complete a transaction, each has a different objective. The consumer does not want to disclose any personal information unnecessarily, and a business would like to collect as much information as possible about its customers so that it can personalize services and advertisements, target marketing efforts, and serve them more successfully. Consumers do appreciate these efforts yet are reluctant to share private information (Hoffman, 2003).

Cookies

Second, search engines also may potentially cause privacy problems by storing the search habits of their customers by using cookies. Their caches also may be a major privacy concern, since Web pages with private information posted by mistake, listserv, or Usenet postings may become available worldwide (Aljifri & Navarro, 2004). In general, cookies may be a privacy threat by saving personal information and recording user habits. The convenience of having preferences

saved does not outweigh the risks associated with allowing cookies access to your private data. There are now many software packages that aid consumers in choosing privacy preferences and blocking cookies (see solutions section).

Google

Finally, the most recent controversy involves Google's Gmail service and Phonebook. Gmail uses powerful search tools to scan its users' e-mails in order to provide them with personalized advertisements. On the one hand, this invades users' private e-mails. However, it is a voluntary service the user agrees to when signing up (Davies, 2004).

SOLUTIONS

There have been many attempts at trying to solve the privacy problem. There are three different types of solutions: governmental regulation, self-regulation, and technological approaches.

Governmental Regulation

Some form of government policy is essential, since in the absence of regulation and legislation to punish privacy-offenders, consumers may be reluctant to share information. However, written privacy policy requires enforcement (O'Brien & Yasnoff, 1999). In addition, given the current bureaucratic nature of legislation, technology advances far faster than the laws created to regulate it. Consequently, self-regulation may be a better solution.

Self-Regulation

There are numerous forms of self-regulation. The Fair Information Practices (U.S.) and the Organization for Economic Co-operation and Development (OECD) Guidelines (International) are both guidelines for protecting computerized records. These guidelines provide a list of policies a company should follow. Another type of self-regulated solution is a privacy seal program such as TRUSTe or Verisign. A business may earn these seals by following the guidelines that the seal company provides. A third kind of self-regulation is opt-in/opt-out policy. Consumers should be able to choose services by opting in or out (Hoffman et al., 1999) and to voluntarily embrace new privacy principles (Smith, 2001). A joint program of privacy policies and seals may provide protection comparable to government laws (Cranor et al., 1999) and may even address new issues faster than legislation.

Technology

Technological solutions also are a viable alternative. Technologies can protect individuals by using encryption, firewalls, spyware, and anonymous and pseudonymous communication. A well-known privacy technology is the Platform for Privacy Preferences (P3P), a World Wide Web Consortium (W3C) project that provides a framework for online interaction and assists users in making informed privacy decisions. In summary, although there seems to be some promise to each of these three alternatives, a combination of government regulation, privacy policies, and technology may be the best solution.

CONCLUSION

Advances in the collection and analysis of personal information have proven to be beneficial to society. At the same time, they have aggravated the innate concern for the protection of privacy. This article has reviewed current issues in the areas of information privacy and its preservation. It has included the differing points of view of those providing the information and those collecting and using it. Since the collection of information entails

both benefits and threats, various suggestions for minimizing the economic costs and maximizing the benefits are discussed.

KEY TERMS

Cookies: A string of text that a Web browser sends to you while you are visiting a Web page. It is saved on your hard drive, and it saves information about you or your computer. The next time you visit this Web site, the information saved in this cookie is sent back to the Web browser to identify you.

Data Mining: A process by which information is extracted from a database or multiple databases using computer programs to match and merge data and create more information.

Fair Information Practices (FIP): Developed in 1973 by the U.S. Department of Health, Education, and Welfare (HEW) to provide guidelines to protect computerized records. These principles are collection, disclosure, accuracy, security, and secondary use. Some scholars categorize the categories as follows: notice, choice, access, security, and contact information (Culnan, 1999; FTC, 2000).

Opt-In/Opt-Out: A strategy that a business may use to set up a default choice (opt-in) in a form that forces a customer, for example, to accept e-mails or give permission to use personal information, unless the customer deliberately decline this option (opt-out).

Organization for Economic Co-operation and Development (OECD) Guidelines: International guidelines for protecting an individual's privacy (similar to the FIP).

Privacy: The right to be left alone and the right to control and manage information about oneself.

Privacy Seals: A seal that a business may put on its Web site (i.e., Verisign or TRUSTe) to show that it is a trustworthy organization that adheres to its privacy policies.

Chapter 6.10
Enhancing E-Business on the Semantic Web through Automatic Multimedia Representation

Manjeet Rege
Wayne State University, USA

Ming Dong
Wayne State University, USA

Farshad Fotouhi
Wayne State University, USA

ABSTRACT

With the evolution of the next generation Web—the Semantic Web—e-business can be expected to grow into a more collaborative effort in which businesses compete with each other by collaborating to provide the best product to a customer. Electronic collaboration involves data interchange with multimedia data being one of them. Digital multimedia data in various formats have increased tremendously in recent years on the Internet. An automated process that can represent multimedia data in a meaningful way for the Semantic Web is highly desired. In this chapter, we propose an automatic multimedia representation system for the Semantic Web. The proposed system learns a statistical model based on the domain specific training data and performs automatic semantic annotation of multimedia data using eXtensible Markup Language (XML) techniques. We demonstrate the advantage of annotating multimedia data using XML over the traditional keyword based approaches and discuss how it can help e-business.

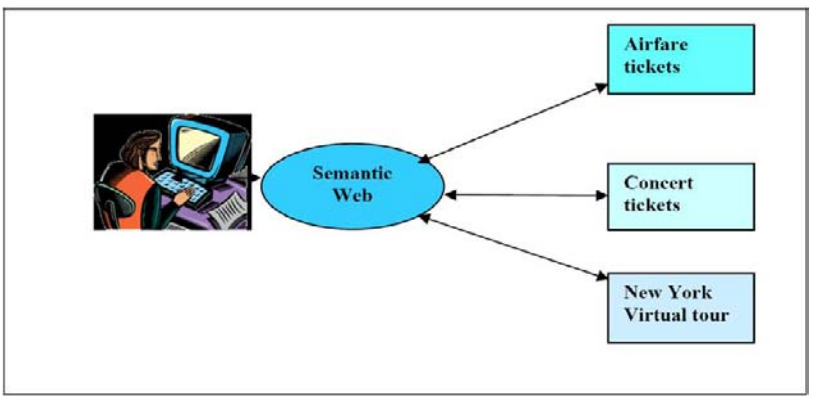
INTRODUCTION

An Internet user typically conducts separate individual e-business transactions to accomplish a certain task. A tourist visiting New York might purchase airfare tickets and tickets to a concert in New York separately. With the evolution of the Semantic Web, as shown in Figure 1, the user can conduct one collaborative e-business transaction for the two purchases. Moreover, he/she can also take a virtual tour of New York city online, which actually might be a collection of all videos, images, and songs on New York appearing anywhere on the World Wide Web. With the continuing growth and reach of the Web, the multimedia data available on it continue to grow on a daily basis. For a successful collaborative e-business, in addition to other kinds of data, it is important to be able to organize and search the multimedia data for the Semantic Web.

With the Semantic Web being the future of the World Wide Web of today, there has to be an efficient way to represent the multimedia data automatically for it. Multimedia data impose a great challenge to document indexing and retrieval as it is highly unstructured and the semantics are implicit in the content of it. Moreover, most of the multimedia contents appearing on the Web have no description available with it in terms of keywords or captions. From the Semantic Web point of view, this information is crucial because it describes the content of multimedia data and would help represent it in a semantically meaningful way. Manual annotation is feasible on a small set of multimedia documents but is not scalable as the number of multimedia documents increases. Hence, performing manual annotation of all Web multimedia data while "moving" them to the Semantic Web domain is an impossible task. This we believe is a major challenge in transforming today's Web multimedia data into tomorrow's Semantic Web data.

In this chapter, we propose a generic automatic multimedia representation solution for the Semantic Web—an XML-based (Bray, Paoli, & Sperberg-McQueen, 1998) automatic multimedia representation system. The proposed system is implemented using images as an example and performs domain-specific annotation using XML. Specifically, our system "learns" from a set of domain-specific training images made available to it a priori. Upon receiving a new image from the Web that belongs to one of the semantic categories the system has learned, the system generates appropriate XML-based annotation for the new image, making it "ready" for the Semantic Web. Although the proposed system has been described from the perspective of images, in general it is

Figure 1. Collaborative e-business scenario on the Semantic Web



applicable to many kinds of multimedia data available on the Web today. To our best knowledge, there has been no work done on automatic multimedia representation for the Semantic Web using the semantics of XML. The proposed system is the first work in this direction.

BACKGROUND

The term *e-business* in general refers to online transactions conducted on the Internet. These are mainly classified into two categories: business-to-consumer (B2C) and business-to-business (B2B). One of the main differences between these two kinds of e-businesses is that B2C, as the name suggests, applies to companies that sell their products or offer services to consumers over the Internet. B2B on the other hand are online transactions conducted between two companies. From its initial introduction in late 1990s, e-business has grown to include services such as car rentals, health services, movie rentals, and online banking. The Web site CIO.com (2006) reports that North American consumers have spent $172 billion shopping online in 2005, up from $38.8 billion in 2000. Moreover, e-business is expected to grow even more in the coming years. By 2010, consumers are expected to spend $329 billion each year online. We expect the evolving Semantic Web to play a significant role in enhancing the way e-business is done today. However, as mentioned in the earlier section, there is a need to represent the multimedia data on the Semantic Web in an efficient way. In the following section, we review some of the related work done on the topic.

Ontology/Schema-Based Approaches

Ontology-based approaches have been frequently used for multimedia annotation and retrieval. Hyvonen, Styrman, and Saarela (2002) proposed ontology-based image retrieval and annotation of graduation ceremony images by creating hierarchical annotation. They used Protégé (n.d.) as the ontology editor for defining the ontology and annotating images. Schreiber, Dubbeldam, Wielemaker, and Wielinga (2001) also performed ontology-based annotation of ape photographs, in which they use the same ontology defining and annotation tool and use Resource Definition Framework (RDF) Schema as the output language. Nagao, Shirai, and Squire (2001) have developed a method for associating external annotations to multimedia data appearing over the Web. Particularly, they discuss video annotation by performing automatic segmentation of video, semiautomatic linking of video segments, and interactive naming of people and objects in video frames. More recently, Rege, Dong, Fotouhi, Siadat, and Zamorano (2005) proposed to annotate human brain images using XML by following the MPEG-7 (Manjunath, 2002) multimedia standard. The advantages of using XML to store meta-information (such as patient name, surgery location, etc.), as well as brain anatomical information, has been demonstrated in a neurosurgical domain. The major drawback of the approaches, mentioned previously, is that the image annotation is performed manually. There is an extra effort needed from the user's side in creating the ontology and performing the detailed annotation. It is highly desirable to have a system that performs automatic semantic annotation of multimedia data on the Internet.

Keyword-Based Annotations

Automatic image annotation using keywords has recently received extensive attention in the research community. Mori, Takahashi, and Oka (1999) developed a co-occurrence model, in which they looked at the co-occurrence of keywords with image regions. Duygulu, Barnard, Freitas, and Forsyth (2002) proposed a method to describe images using a vocabulary of blobs. First, regions are created using a segmentation algorithm. For

each region, features are computed and then blobs are generated by clustering the image features for these regions across images. Finally, a translation model translates the set of blobs of an image to a set of keywords. Jeon, Lavrenko, and Manmatha (2003) introduced a cross-media relevance model that learns the joint distribution of a set of regions and a set of keywords rather than the correspondence between a single region and a single keyword. Feng, Manmatha, and Lavrenko (2004) proposed a method of automatic annotation by partitioning each image into a set of rectangular regions. The joint distribution of the keyword annotations and low-level features is computed from the training set and used to annotate testing images. High annotation accuracy has been reported. The readers are referred to Barnard, Duygulu, Freitas, and Forsyth (2003) for a comprehensive review on this topic. As we point out in the section, "XML-Based Annotation," keyword annotations do not fully express the semantic meaning embedded in the multimedia data. In this paper, we propose an Automatic Multimedia Representation System for the Semantic Web using the semantics of XML, which enables efficient multimedia annotation and retrieval based on the domain knowledge. The proposed work is the first attempt in this direction.

PROPOSED FRAMEWORK

In order to represent multimedia data for the Semantic Web, we propose to perform automatic multimedia annotation using XML techniques. Though the proposed framework is applicable to multimedia data in general, we provide details about the framework using image annotations as a case study.

XML-Based Annotation

Annotations are domain-specific semantic information assigned with the help of a domain expert to semantically enrich the data. The traditional approach practiced by image repository librarians is to annotate each image manually with keywords or captions and then search on those captions or keywords using a conventional text search engine. The rationale here is that the keywords capture the semantic content of the image and help in retrieving the images. This technique is also used by television news organizations to retrieve file footage from their videos. Such techniques allow text queries and are successful in finding the relevant pictures. The main disadvantage with manual annotations is the cost and difficulty of scaling it to large numbers of images.

MPEG-7 (Manjunath, 2002, p. 8) describes the content—"the bits about the bits"—of a multimedia file such as an image or a video clip. The MPEG-7 standard has been developed after many rounds of careful discussion. It is expected that this standard would be used in searching and retrieving for all types of media objects. It proposes to store low-level image features, annotations, and other meta-information in one XML file that contains a reference to the location of the corresponding image file. XML has brought great features and promising prospects to the future of the Semantic Web and will continue to play an important role in its development. XML keeps content, structure, and representation apart and is a much more adequate means for knowledge representation. It can represent semantic properties through its syntactic structure, that is, by the nesting or sequentially ordering relationship among elements (XML tags). The advantage of annotating multimedia using XML can best be explained with the help of an example. Suppose we have a New York image (shown in Figure 2) with keywords annotation of Statue of Liberty, Sea, Clouds, Sky. Instead of simply using keywords as annotation for this image, consider now that the same image is represented in an XML format.

Note that the XML representation of the image can conform to any domain-specific XML schema. For the sake of illustration, consider

the XML schema and the corresponding XML representation of the image shown in Figure 3. This XML schema stores foreground and background object information along with other meta-information with keywords along various paths of the XML file. Compared with keyword-based approaches, the XML paths from the root node to the keywords are able to fully express the semantic meaning of the multimedia data. In the case of the New York image, semantically meaningful XML annotations would be "image/semantic/foreground/object=Statue of Liberty, image/semantic/foreground/ object = Sea, image/semantic/ background/ object = Sky, image/semantic/background /object =Clouds". The semantics in XML paths provides us with an added advantage by differentiating the objects in the foreground and background and giving more meaningful annotation.

We emphasize that the annotation performed using our approach is domain-specific knowledge. The same image can have different annotation under a different XML schema that highlights certain semantic characteristics of importance pertaining to that domain knowledge. We simply use the schema of Figure 3 that presents image foreground and background object information as a running example.

Overview of System Architecture

The goal of the proposed system is to represent multimedia data obtained from the Web in a meaningful XML format. Consequently, this data can be "moved" to the Semantic Web in an automatic and efficient way. For example, as shown in Figure 4, the system first receives an image from the Web. The image could be received by a *Web image provider* which is an independent module outside of the system that simply fetches domain-specific images from the Web and passes them onto our system. The Web image provider could also be a "Web spider" that "crawls" among domain-specific Web data sources and procures relevant images. The image is then preprocessed by two other modules, namely, *image divider* and *feature extractor*. An image usually contains several regions. Extracting low-level features from different image regions is typically the first step of automatic image annotation since regions may have different contents and represent different semantic meaning. The image regions could be determined through either image segmentation (Shi & Malik, 1997) or image cutting in the image divider. For low-level feature extraction, we used some of the features standardized by MPEG-7.

The low-level features extracted from all the regions are passed on to the *automatic annotator*. This module learns a statistical model that links image regions and XML annotation paths from a set of domain-specific training images. The training image database can contain images belonging to various semantic categories represented and annotated in XML format. The annotator learns to annotate new images that belong to at least one of the many semantic categories that the

annotator has been trained on. The output of the automatic annotator is an XML representation of the image.

Statistical Model for Automatic Annotation

In general, image segmentation is a computationally expensive as well as an erroneous task (Feng et al., 2004). As an alternative simple solution, we have the image divider partition each image into a set of rectangular regions of equal sizes. The feature extractor extracts low-level features from each rectangular region of every image and constructs a feature vector. By learning the joint probability distribution of XML annotation paths and low-level image features, we perform the automatic annotation of a new image.

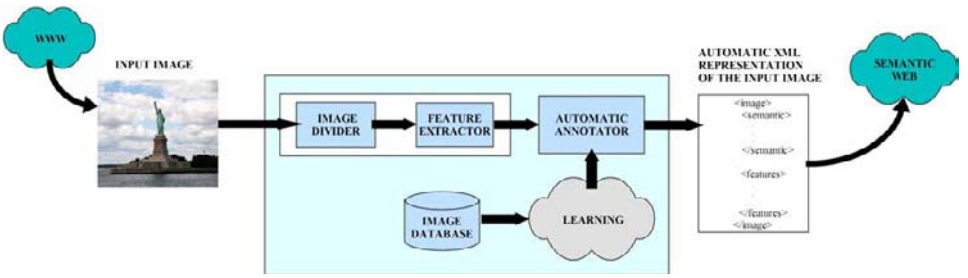
Let X denote the set of XML annotation paths, T denote the domain-specific training images in XML format, and let t be an image belonging to T. Let x_t be a subset of X containing the annotation paths for t. Also, assume that each image is divided into n rectangular regions of equal size.

Consider a new image q not in the training set. Let $f_q = \{f_{q1}, f_{q2}, \ldots..f_{qn}\}$ denote the feature vector for q. In order to perform automatic annotation of q, we model the joint probability of f_q and any arbitrary annotation path subset x of X as follows,

$$P(x, f_q) = P(x, f_{q1}, f_{q2}, \ldots..., f_{qn}) \quad (1)$$

We use the training set T of annotated images to estimate the joint probability of observing *x* and $\{f_{q1}, f_{q2,\ldots\ldots..,} f_{qn}\}$ by computing the expectation over

Figure 4. System architecture



all the images in the training set.

(2)

$$P(x, f_{q1}, f_{q2}, \ldots, f_{qn}) = \sum_{t \in T} P(t)\, P(x, f_{q1}, f_{q2}, \ldots, f_{qn} \mid t)$$

We assume that the events of observing x and $f_{q1,}$ $f_{q2,}$ f_{qn} are mutually independent of each other and express the joint probability in terms of P_A, P_B and P_C as follows:

(3)

$$P(x, f_{q1}, f_{q2}, \ldots f_{qn}) = \sum_{t \in T} \{ P_A(t) \prod_{a} P_B(f_a|t) \prod_{path \in x} P_C(path|t) \prod_{path \notin x} (1 - P_C(path|t)) \}$$

where P_A is the prior probability of selecting each training image, P_B is the density function responsible for modeling the feature vectors, and P_C is a multiple Bernoulli distribution for modeling the XML annotation paths.

In the absence of any prior knowledge of the training set, we assume that P_A follows a uniform prior and can be expressed as:

$$P_A = \frac{1}{\| T \|} \quad (4)$$

where ||T|| is the size of the training set. For the distribution P_B, we use a nonparametric, kernel-based density estimate:

$$P_B(f|t) = \frac{1}{n} \sum_i \frac{\exp\{-(f - f_i)^T \Sigma^{-1} (f - f_i)\}}{\sqrt{2^k \prod^k |\Sigma|}} \quad (5)$$

where f_i belongs to $\{f_1, f_2, \ldots, f_n\}$ the set of all low-level features computed for each rectangular region of $\sum$ image t. is the diagonal covariance matrix which is constructed empirically for best annotation performance.

In the XML representation of images, every annotation path can either occur or might not occur at all for an image. Moreover, as we annotate images based on object presence and not on prominence in an image, an annotation path if it occurs can occur—at most—once in the XML representation of the image. As a result, it is reasonable to assume that the density function P_C follows a multiple Bernoulli distribution as follows:

$$P_C(path|t) = \frac{(\gamma \alpha_{path,t} + N_{path})}{(\gamma + \| T \|)} \quad (6)$$

where γ is a smoothing parameter, if the path occurs in the annotation of image *t*, else it is zero. N_{path} is the total number of training images that contain this *path* in their annotation.

EXPERIMENTAL RESULTS

Our image database contains 1,500 images obtained from the Corel data set, comprising 15 image categories with 100 images in each category. The Corel image data set contains images from different semantic categories with keyword annotations performed by Corel employees. In order to conduct our experiments, we require a

training image database representing images in XML format. Each XML file should contain annotation, low-level features, and other meta-information stored along different XML paths. In the absence of such a publicly available data, we had to manually convert each image in the database to an XML format conforming to the schema shown in Figure 3. We performed our experiments on five randomly selected image categories. Each image category represents a distinct semantic concept. In the experiments, 70% of the data are randomly selected as the training set while the remaining were used for testing.

Automatic Annotation Results

Given a test image, we calculate the joint probability of the low-level feature vector and the XML annotation paths in the training set. We select the top four paths with the highest joint probability as the annotation for the image. Compared with other approaches in image annotation (Duygulu et al., 2002; Feng et al., 2004), our annotation results provide more meaningful description of a given image.

Figure 5 shows some examples of our annotation results. We can clearly see that the XML-path-based annotation contains richer semantic meaning than the original keyword provided by Corel. We evaluate the image annotation performance in terms of recall and precision. The recall and precision for every annotation path in the test set is computed as follows:

$$\text{recall} = \frac{q}{r}$$

$$\text{precision} = \frac{q}{s}$$

where q is the number of images correctly annotated by an annotation path, r is the number of images having that annotation path in the test set, and s is the number of images annotated by the same path. In Table 1 we report the results for all the 148 paths in the test set as well as the 23 best paths as in Duygulu et al. (2002) and Feng et al. (2004).

Retrieval Results

Given specific query criteria, XML representation helps in efficient retrieval of images over

Figure 5. Examples of top annotation in comparison with Corel keyword annotation

Mean per-path precision	0.21	0.73

the Semantic Web. Suppose a user wants to find images that have an *airplane* in the background and *people* in the foreground. State-of-the-art search engines require the user to supply individual keywords such as "airplane," "people," and so forth or any combination of keywords as a query. The union of the retrieved images of all possible combinations of the aforementioned query keywords is sure to have images satisfying the user specified criteria.

However, a typical search engine user searching for images is unlikely to view beyond the first 15-20 retrievals, which may be irrelevant in this case. As a result, the user query in this scenario is unanswered in spite of images satisfying the specified criteria being present on the Web. With the proposed framework, the query could be answered in an efficient way. Since all the images on the Semantic Web are represented in an XML format, we can use XML querying technologies such as XQuery (Chamberlin, Florescu, Robie, Simeon, & Stefanascu, 2001) and XPath (Clark & DeRose, 1999) to retrieve images for the query "image/semantic/background/object = plane & image/semantic/foreground/object = people". This is unachievable with keyword-based queries and hence is a major contribution of the proposed work.

Figure 6 shows some examples of the retrieval results. In Table 2, we also report the mean average precision obtained for ranked retrieval as in Feng et al. (2004).

Since the proposed work is the first one of its kind to automatically annotate images using XML

Figure 6. Ranked retrieval for the query image/semantic/background/object = "sky"

Table 2. Mean average precision results

All 148 paths	**Paths with recall > 0**
0.34	0.38

paths, we were unable to make a direct comparison with any other annotation model. However, our annotation and retrieval results are comparable to the ones obtained by Duygulu et al. (2002) and Feng et al. (2004).

CONCLUSION AND DISCUSSION

With the rapid development of digital photography, more and more people are able to share their personal photographs and home videos on the Internet. Many organizations have large image and video collections in digital format available for online access. For example, film producers advertise movies through interactive preview clips. News broadcasting corporations post photographs and video clips of current events on their respective Web sites. Music companies have audio files of their music albums made available to the public online. Companies concerning the travel and tourism industry have extensive digital archives of popular tourist attractions on their Web sites. As this multimedia data is available—although scattered across the Web—an efficient use of the data resource is not being made. With the evolution of the Semantic Web, there is an immediate need for a semantic representation of these multimedia resources. Since the Web is an infinite source of multimedia data, a manual representation of the data for the Semantic Web is virtually impossible. We present the Automatic Multimedia Representation System that annotates multimedia data on the Web using state-of-the art XML technologies, thus making it "ready" for the Semantic Web.

We show that the proposed XML annotation has a more semantic meaning over the traditional keyword-based annotation. We explain the proposed work by performing a case study of images, which in general is applicable to multimedia data available on the Web.

The major contributions of the proposed work from the perspective of multimedia data sources representation can be stated as follows:

- **Multimedia annotation:** Most of the multimedia data appearing on the World Wide Web are unannotated. With the proposed system, it would be possible to annotate this data and represent it in a meaningful XML format. This we believe would enormously help in "moving" multimedia data from World Wide Web to the Semantic Web.
- **Multimedia retrieval:** Due to representation of multimedia data in XML format, the user has an advantage to perform a complex semantic query instead of the traditional keyword based.
- **Multimedia knowledge discovery:** By having multimedia data appear in an XML format, it will greatly help intelligent Web agents to perform Semantic Web mining for multimedia knowledge discovery.

From an e-business point of view, semantically represented and well-organized Web data sources can significantly help the future of a *collaborative* e-business by the aid of intelligent Web agents. For example, an agent can perform autonomous tasks such as interact with travel Web sites and obtain attractive vacation packages where the users can bid for a particular vacation package or receive the best price for a book across all the booksellers. It is important to note that in addition to multimedia data, once other data sources are also represented in accordance with the spirit of the Semantic Web, the opportunities for collaborative e-business tasks are endless.

Chapter 6.11
Digital Multimedia Broadcasting (DMB) in Korea:
Convergence and its Regulatory Implications

Seung Baek
Hanyang University, Korea

Bong Jun Kim
Korea Telecommunications (KT) Marketing Laboratory, Korea

ABSTRACT

The launch of portable Internet, alongside mobile Internet technology and cellular technology, is a new milestone, converging wireless with wired technology. Along with these new technologies, a new telecommunication service has been introduced and has received much attention from the Korean public. This is the Digital Multimedia Broadcasting (DMB) service. DMB is a digital multimedia service combining telecommunications with broadcasting technologies. DMB enables users to watch various multimedia contents on their phone screens while they are on the move. Since DMB services in Korea are the first in the world, the Korean Government has much interest in DMB services. However, the repeated failures in establishing a regulatory framework for DMB and ill-defined roles of players in the DMB industry interfere the diffusion of DMB in the Korean market. As the convergence of broadcasting and telecommunications makes progress, proper modifications of existing regulatory frameworks should be made in order to guarantee success of DMB service in Korea. This chapter reviews DMB technology, its business model, its market structure, and its policy. In particular, it explores business opportunities around DMB services and identifies major issues that must be solved to launch DMB services successfully.

INTRODUCTION

In Korea, the number of Internet users has been growing rapidly, nearly doubling each year since

1997. What is even more interesting is that most Internet users subscribe to high-speed Internet service. In 2001, the number of subscribers per 100 people was 21.8 people in Korea (about 40% of all Internet users), 4.5 people in the United States (about 9% of Internet users), and 2.2 people in Japan (5% of Internet users). This dramatic expansion of the high-speed Internet service has even received worldwide attention. The International Telecommunication Union (ITU) and the Organisation for Economic Co-operation and Development (OECD) announced that Korea ranked first in the diffusion of high-speed Internet service. Ninety-seven percent of all households in Korea have some way of connecting to the Internet and 60% of all households in Korea access the high-speed Internet.

In Korea, the phenomenal growth of ownership of cellular phones was not a government initiative, rather a private industry-driven one. Due to the highly efficient electronics industry which was able to manufacture low-cost/high-capacity cellular phones, the Korean public quickly adopted the use of cellular phones in their everyday lives. According to statistics, almost 90% of all adults now own a cellular phone, which makes Korea the country with highest ownership of cellular phones in the world. Recently, the use of mobile Internet through various handsets, such as cellular phones and personal digital assistants (PDAs), has become popular.

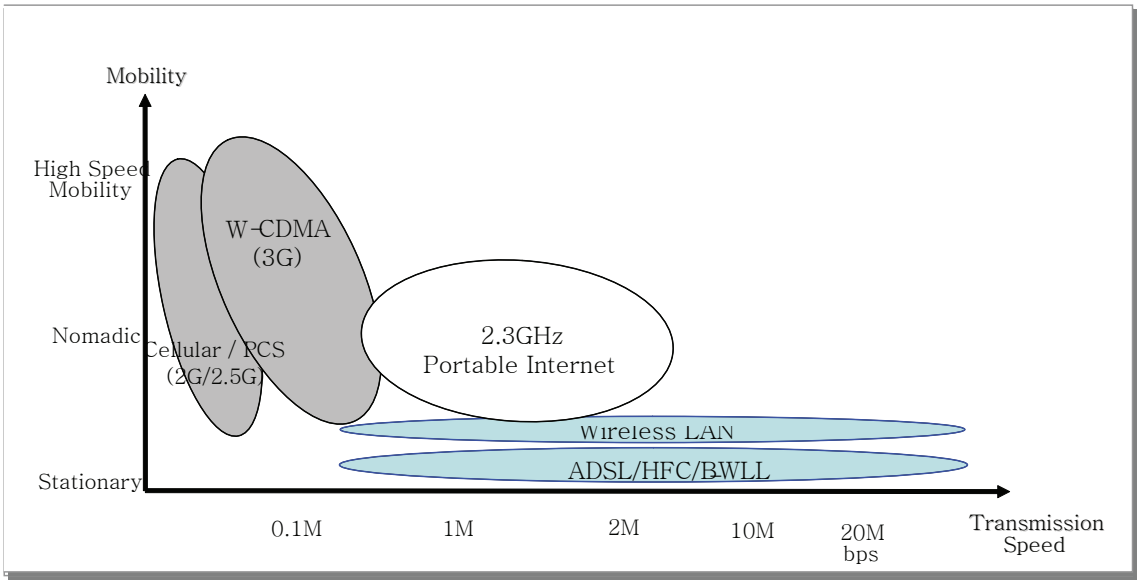
Now, many Korean users have utilized the Internet for personal communications (e.g., e-mail) and information searching. As the user population of the high-speed Internet service is growing quickly in Korea, many users are more inclined to use the Internet for multimedia entertainment, such as games, movies, and music. The high-speed Internet service shifts its main usage to entertainment. In terms of mobile Internet, its main usage is also concentrated on entertainment, such as ring/avatar downloads.

The launch of portable Internet, alongside mobile Internet technology and cellular technology, is a new milestone, converging wireless with wired technology. Along with these new technologies, a new telecommunication service has been introduced and has received much attention from the Korean public. This is the Digital Multimedia Broadcasting (DMB) service. DMB is a digital multimedia service combining telecommunications with broadcasting technologies. DMB enables users to watch various multimedia contents on their phone screens while they are on the move. By combining telecommunication and broadcasting technologies, DMB adds tremendous value to broadcasting. Traditionally, broadcasting technology is used to transmit information to many unspecified persons (one-to-many, one-way communication), and it is very difficult to watch TV while on the move. Whereas telecommunication technology allows individual communications (one-to-one, two-way communication) and it is easy to provide personalized services.

DMB, selected as one of the 10 new-growth engine sectors—in other words, one of the 10 most promising industries to propel Korea toward its goal of passing the $20,000 mark in GDP per capita—opens up a vast new horizon for broadcasting, making the most of strengths and specificities of different media, including terrestrial, cable, and satellite broadcasts. Economic and social ripple effects to be expected from DMB also are certainly substantial.

The question remains, however, as to whether DMB can indeed stake out its own market in Korea, as CDMA or the high-speed Internet has done in the past. The answers to this question are so far mutually contradictory even among experts. Figure 1 illustrates the respective positions of different types of telecommunication services in Korea, from which the place of DMB can be roughly deduced. More optimistic onlookers hold the view that DMB, by overcoming the one-way services thus far provided by the mobile Internet or the HSDPA-based mobile Internet, and by wooing over customers with more competitive prices, will be able to create its own niche. The

Figure 1. Telecommunication services positioning in Korea



opposing view holds that the market strategy of putting faith in DMB as a killer application is blunted by the fact that many of its supposedly killer service features are already offered by mobile Internet or HSDPA-based mobile Internet services. This redundancy has the implication that consumers constituting the demand source for DMB may also overlap with those making up the existing portable multimedia service market. In other words, DMB may turn out to be merely a complementary service, remedying some of the weaknesses of competitor services.

As predictions on the market viability of DMB remain divided among onlookers, what place, then, will DMB actually occupy within Korea's telecommunications market and how will it evolve within it? And what would be the response strategies by communications carriers? The objective of this chapter is to offer answers to some of these essential questions regarding the prospect of DMB in the domestic market.

DIGITAL MULTIMEDIA BROADCASTING (DMB)

DMB Technology

Broadcasting is quickly moving into the era of digitalization by replacing traditional analog broadcasting technology with digital broadcasting technology. In 1997, the Ministry of Information and Communications (MIC) created a committee for terrestrial digital broadcasting. This committee mainly focused on the shift from analog radio broadcasting to digital radio broadcasting. At that time, the committee investigated various ways to launch the terrestrial Digital Audio Broadcasting (DAB) service into the Korean market. As telecommunication companies expressed their interests in DAB, many companies became interested on satellite DAB as well as terrestrial DAB. DAB services enable customers to receive CD-like quality radio programs, even in the car, without any annoying interference and signal distortion. Aside from distortion-free reception and CD-quality sound, DAB offers further advantages as it has been designed for the multimedia age. DAB can

carry not only audio, but also text, pictures, data, and even videos. In 2002, by adding multimedia components to DAB, MIC announced a new service, called DMB (digital multimedia broadcasting), as a way to accelerate the convergence of telecommunication and broadcasting services. DMB services can be categorized into terrestrial DMB and satellite DMB.

Terrestrial DMB

Transmission of TV and radio signals using ground-based transmitters in a terrestrial network is traditionally the most used and known distribution form. End users can receive the signals through reception roofs or in-house antennas. This distribution form can also be used for digital TV. As shown in Figure 2, once terrestrial DMB integrates various multimedia contents by using multiplexers and orthogonal frequency division multiplex (OFDM) modulators, it transmits these integrated multimedia contents through ground-based transmitters. In 2001, MIC chose Eureka-147 as a standard for terrestrial DMB.

Satellite DMB

Unlike terrestrial DMB, satellite DMB transmits signals through satellites. Terrestrial DMB normally covers limited areas, whereas satellite DMB can transmit signals far away from a country's border. In addition, satellite DMB enables the signals to be transmitted with high technical quality. The high capacity of satellite DMB provides the opportunities to broadcast more channels and various digital services. However, compared with terrestrial DMB, satellite DMB is not cost efficient. As shown in Figure 3, satellite DMB transmits signals through satellites. For fringe areas, it retransmits the signals by using gap fillers. This is a major difference between regular satellite broadcasting and satellite DMB. The world's first DMB satellite, Hanbyol (MBSat), was successfully launched in March 2004. The

Figure 2. Terrestrial DMB

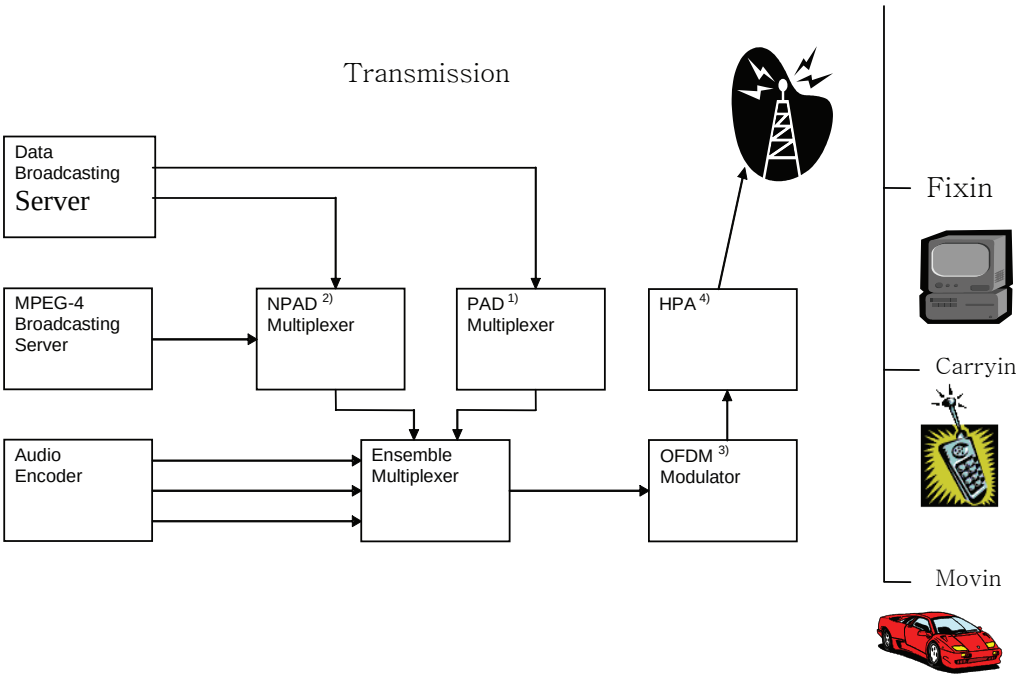


Figure 3. Satellite DMB

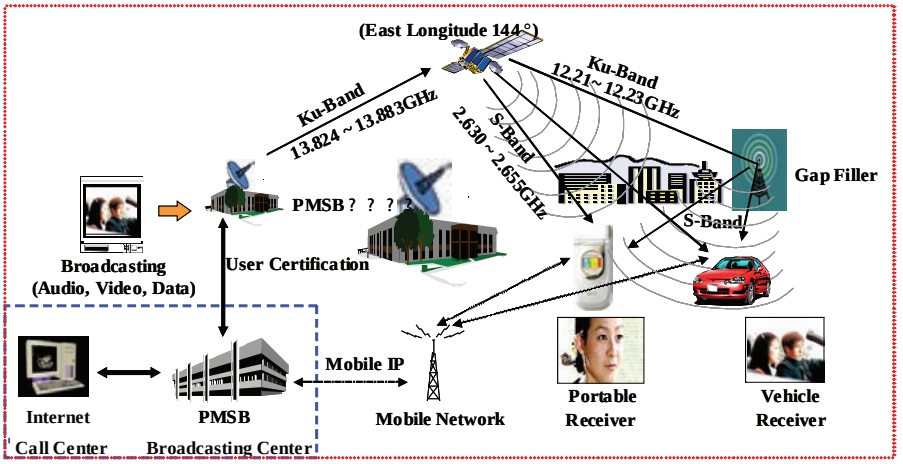

satellite was launched by a joint venture between SK Telecom affiliated TU Media and Japan's Mobile Broadcasting Corporation (MBCo). SK Telecom and MBCo are responsible for 34.66% and 65.34% of the total cost for launching the satellite, respectively. Besides SK Telecom, KT, a giant Korean telecommunication company, also expressed its interests in satellite DMB and jumped into the DMB business. From ITU (International Telecommunication Union), KT already occupied frequency band that it is going to use for its satellite DMB service in future. Since MIC announced DMB services in 2002, two giant Korean telecommunication companies, SK Telecom and KT, competed with each other to gain a competitive advantage in the evolving satellite DMB industry. Since two companies plan to use different standards for their own DMB services (SK Telecom uses System E and KT uses System A), their competitions were fierce, rather than collaborative. In 2003, MIC selected System E as a standard for satellite DMB. At that moment, by focusing more on wireless Internet business, KT gave up the satellite DMB business, and SK Telecom-affiliated TU Media has led the satellite DMB business ever since.

As the voice communication market has been saturated, telecommunication companies and MIC have looked for ways to make profit by using existing infrastructures. Recently, MIC announced the IT 8-3-9 Strategy. The IT 8-3-9 Strategy proposes eight new telecommunication services, three telecommunication infrastructures, and nine application areas as concentrated items that the Korean Government has decided to foster (see Table 1). It is an ambitious plan by the Korean Government to promote its competitiveness in the global market. Since DMB services in Korea are the first in the world, the Korean Government has much interest in DMB services. On the other hand, it imposes new political and regulatory challenges and makes rethinking and redesigns of the existing regulatory framework.

DMB Services and Business Models

DMB can be defined as a digital broadcasting medium, capable of providing stable transmission of CD-quality audio, data, and video content to fixed or portable reception devices. It is divided into two categories depending on the signals used: terrestrial DMB and satellite DMB. Figure 4 shows the differences between existing broadcasting services and DMB services. Both terrestrial DMB and satellite DMB allow customers to watch TV on their various handsets, such

Table 1. IT 8-3-9 strategy

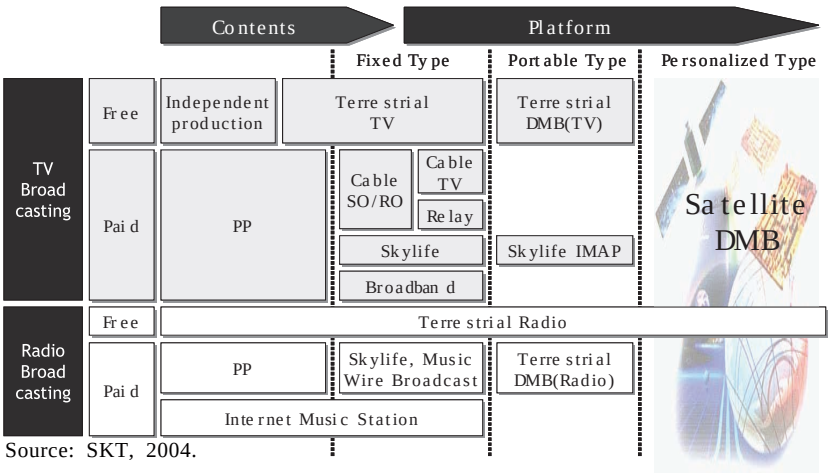
Figure 4. DMB service areas



Source: SKT, 2004.

as PDAs or cellular phones, while on the move. Furthermore, by integrating existing telecommunication infrastructures and the Internet, DMB makes interactive, and personalized broadcasting possible.

In principle, terrestrial DBM is a free service for customers. Major income sources of terrestrial DMB operators heavily depend on advertisement sales, whereas satellite DMB operators generate income based on subscription charges. Therefore, it is very critical for satellite DMB to differentiate its contents from terrestrial DMB and to provide its services for a reasonable price. On the other hand, it is crucial for terrestrial DMB to acquire various contents in order to compete with satellite DMB.

The DMB service of Korea is one of the national new-growth powers that can provide domestic telecommunication and broadcasting markets with vital energies. Furthermore, DMB, as a national exporting industry, is expected to have strong ripple effects on the Korean economy.

Table 2. DMB service economic spread effect

	2005	2006	2007	2008	2009	2010
Production Effect (Billion Won)	5,924 1	1,995	20,496	27,886	36,917	43,660
Employment Effect (Thousand People)	6.8	13.7	23.1	31.1	40.9	48.0

Figure 5. Equity composition of TU Media

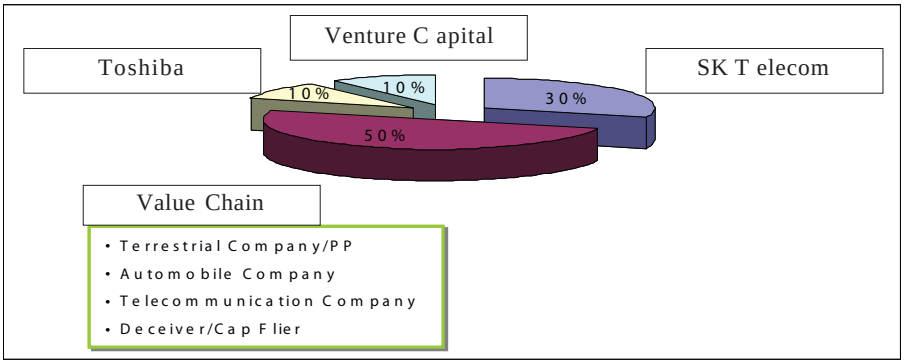


Table 2 summarizes the economic effects of DMB service.

The industry of terrestrial DMB is supposed to be led by three major Korean terrestrial broadcasting companies (KBS, MBC, and SBS). Compared with the satellite DMB industry led by SK Telecom, terrestrial DMB industry does not have many business leaders who are able to or intend to invest large amount of money into terrestrial DMB. From all aspects, including service variety, service coverage, and service quality, terrestrial DMB is inferior to satellite DMB. However, to diffuse DMB service into Korean market at the beginning, the role of terrestrial DMB is crucial due to free service. Since many companies, especially broadcasting companies, cannot guarantee the returns to their investments, they hesitate to participate in terrestrial DMB business actively. At this time, KBS, the nation's representative public broadcaster, is preparing for a terrestrial DMB service, from developing technology of terrestrial DMB to experimenting media. Since KBS has a monopoly in the terrestrial DMB market, other competing broadcasting companies, such as MBC and SBS, recently decided to invest quota in satellite DMB which can be a competitor of terrestrial DMB. It causes conflicts among the three major terrestrial broadcasting companies. From a public broadcaster's point of view, KBS cannot participate in launching charged services like other private broadcasters.

In terms of satellite DMB, SK Telecom, a market leader of the mobile communication, and KT, a market leader of wire communication, were preparing for satellite DMB enterprise together. However, the recent withdrawal of KT from satellite DMB enterprise enables SKT-affiliated TU Media to prepare a satellite DMB enterprise by itself (see Figure 5).

MARKET ISSUES

The Relationship Between Terrestrial DMB and Satellite DMB Players

With the exception that terrestrial DMB and satellite DMB do not share the same frequency band and use different transmission media/paths, they are virtually identical services. Regarding to revenue sources, the main income source of terrestrial DMB is advertising, whereas the income source of satellite DMB is a subscription charge. In terms of coverage, unlike satellite DMB providing nationwide services from the beginning, terrestrial DMB service is restricted to the Seoul and several metropolitan areas early in its commercialization. As DMB service becomes popular, it will offer national coverage in conjunction with DTV migration. Considering the traditional reticence exhibited by the Korean public toward fee-based services, without retransmission by terrestrial TVs of satellite DMB, satellite DMB service may find itself at a significant competitive disadvantage.

With new developments taking place in the telecommunication and broadcasting markets, it might be difficult to clearly define roles of terrestrial DMB and satellite DMB and their mutual relationship. If policy assigns and regulates the respective territories of these two services, it may help to avoid the overlapping of these two services, but it may also prove to be an overintervention, hurting DMB market takeoff. On the other hand, by entirely depending on the market and by lifting or loosening restrictions, the two services are likely to develop a competing relationship with each other. It is quite a difficult task for the Korean Government to balance between restrictions and free competition.

Another potential problem is passive investment of existing terrestrial broadcasting companies into terrestrial DMB. Unlike satellite DMB being expected continuous large-scale investments by major telecommunication companies and others, terrestrial DMB might experience difficulty in obtaining such large investments, due to the lack of well-defined business models. If such scenarios turn out to be true, this will certainly be a hindrance to continuous content development. It can ultimately result in the stagnation of the terrestrial DMB market. Although the fact that terrestrial DMB offers free services might be an appealing formula for the market in the short run, terrestrial DMB might be beaten out of the competition with satellite DMB, owing to the lack of resources for developmental activities. Moreover, to use network effects, satellite DMB players may reduce subscription prices in time. In the beginning, the Korean government might need to provide strong incentives that enable terrestrial broadcasting companies to invest huge amounts of money into terrestrial DMB.

From the viewpoints of service coverage, diversity of contents, and investment size and intention, things are not going to get any brighter for terrestrial DMB. Because the Korean government has a tendency to implement a market-centered policy in the DMB market, the relationship between the two services may inevitably turn out to be competitive. Under this situation, there is high possibility that the terrestrial DMB market will collapse. Accordingly, a policy helping the two services to form a complementary relationship with each other will be welcome for long-term development of this market.

The Relationship With Other Competitive Services

In Korea's communications service market, besides standard mobile wireless data services, there are various services. Among them, WiBro service recently received much attention from the public. It was launched in February 2005. WiBro service is an official name of Korea's portable Internet service. It is a new-concept, wireless high-speed Internet service using the 2.3GHz band, enabling indoor and outdoor reception by

devices moving even at nomadic speed. Many Korean telecommunication companies, including SK Telecom, KT, and Dacom, are applying for its license. Many experts forecast that its ripple effects are almost comparable to those caused by voice mobile communications services half a decade ago. However, a simultaneous launch of two similar services, DMB service and WiBro service, can reduce the possibility of successful market penetration in the short run. In spite of the risk, these new services will play a crucial role for the industry. By identifying the relationship between DMB service and WiBro service, we can investigate ways that make the two services more competitive. This session examines their relationships from three different areas of interest.

Service Coverage and Content Variety

In the case of WiBro, it is practically impossible to offer a nationwide coverage during the initial stage after the service launch. Although it has the national coverage at later stages, it still has shadow zones in urban downtown sections. In regards to DMB, satellite DMB can easily offer national coverage, whereas terrestrial DMB is limited to Seoul and some metropolitan areas. By using special transporters, both terrestrial DMB and WiBro can cover shadow zones (including downtown districts and underground) even during early stages of commercialization.

In terms of the variety of content provided, while WiBro service offers a full spectrum of contents, ranging from information to entertainment, DMB service focuses exclusively on multimedia entertainment programs, with only a limited segment dedicated to information such as weather forecast service in collaboration with the Korea Meteorological Administration. In terms of live broadcasting, WiBro, unable to provide real-time TV broadcasting, appears less competitive than DMB, transmitting live broadcasting and contents. So far, terrestrial TV content is only supplied through terrestrial DMB. Also, satellite DMB service is going to retransmit terrestrial TV contents. If both terrestrial DMB and satellite DMB retransmit regular terrestrial TV contents, WiBro service will be inferior to DMB service. According to a survey on DMB demand conducted by ETRI in 2004, 41.1% of sampled respondents said they would be interested in subscribing to a DMB service, if DMB retransmitted TV contents in addition to DMB's own programs. Only 17.1% of the respondents were interested in DMB, in the case where DMB provided only its own programming.

Figure 6. Preferences of WiBro service contents

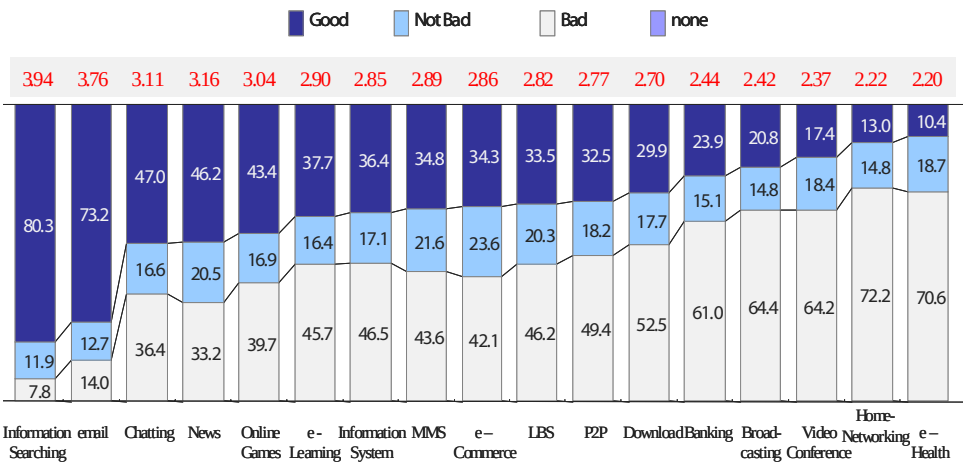

Figure 7. Preferences of DMB service contents

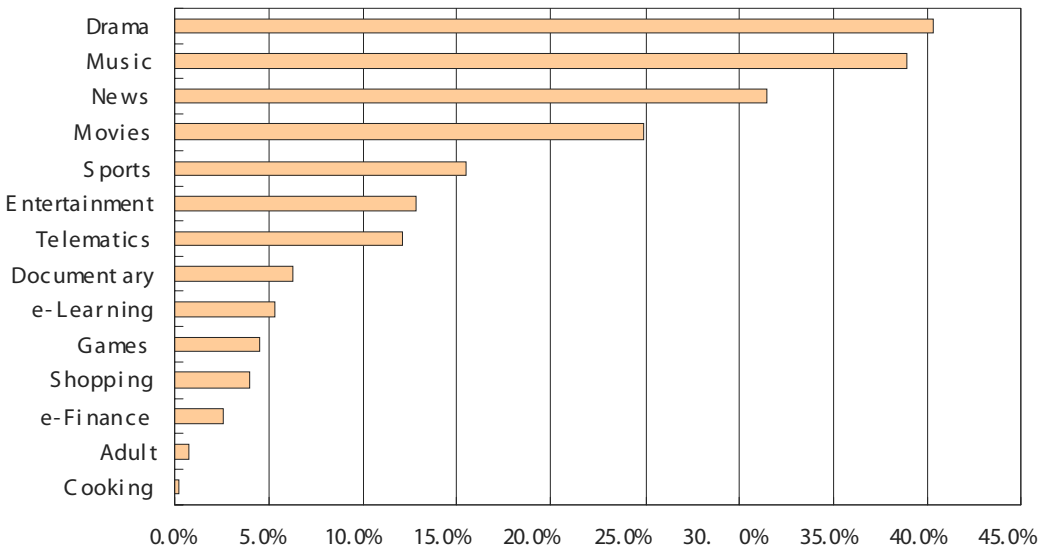


Customers

As can be seen in Figure 6, in the case of WiBro, the respondents of the ETRI survey (2004) expressed a higher degree of interest for information searching, e-mail, and news. By age group, the younger the respondents, the stronger the appeal for contents such as chatting, games, and messaging. In comparison, older age groups showed more interest in value-added services which could yield practical benefits.

Contrasting responses were obtained regarding DMB service (see Figure 7). Drama series, music, and news were the preferred types of content that attracted respondents toward DMB. E-finance and shopping-related contents appeared to weigh in relatively little in their interest in DMB. By age group, teenagers exhibited a strong preference for music and entertainment, while respondents in their 20s and early 30s mostly favored films and animations, and those in their mid-30s or older, were interested in sports broadcast.

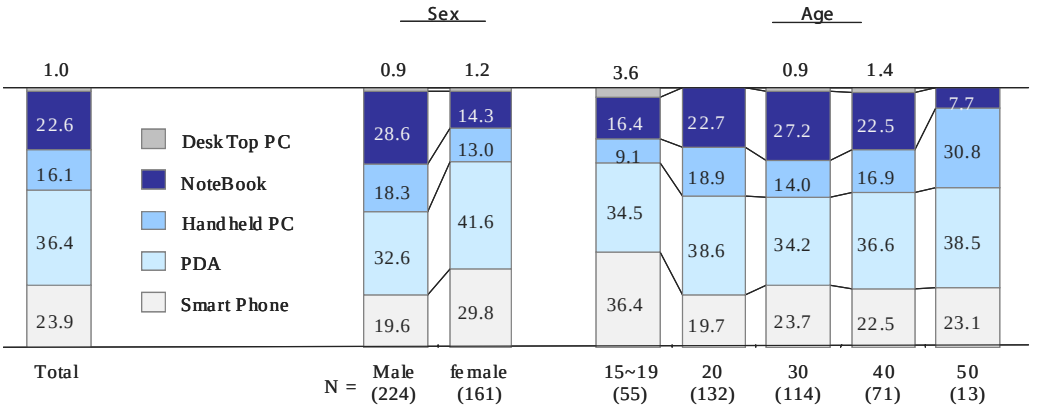
Receiving Devices

Figure 8 indicates that PDA and notebook computers were the preferred receiving devices for WiBro service across all age groups.

Regarding DMB, handheld devices (61.2%) and car-mounted devices (23.8%) were the preferred devices. Respondents showed only a low level of interest in stand-alone devices (4.4%). Meanwhile, an overwhelming majority of respondents favored a dual-reception device enabling the reception of both terrestrial and satellite DMB (80%). Moreover, as many as 74% answered they would wait with their DMB subscription until the dual-reception devices became available.

This survey finds several common features shared by the two services. First of all, they are both multimedia services, and both services target teens as their principal customer group. Moreover, they are portable services focusing on the customer group primarily interested in using the services under an outdoor and mobile environment. On the other hand, the survey results also indicate a number of differences. First,

Figure 8. WiBro service receiving device preference



WiBro service is perceived as an information and e-commerce-oriented service, in contrast to DMB, which is extensively associated with multimedia services. The preferred receiving devices for WiBro and DMB services were also clearly distinct. The second major difference has to do with service coverage. While WiBro service coverage is limited during the early stages of its implementation, satellite DMB can offer nation-wide coverage from the outset. Table 3 compares WiBro with DMB.

If terrestrial and satellite DMB launch as competing services, it is likely to reduce their appeal to customers and to ultimately weaken their competitiveness vis-à-vis other services. Furthermore, although two services partially overlap with each other in service content and target customer groups, it is not a major problem in building a collaborative relationship between the two services. This phenomenon has occurred in many other products and services. In fact, there is a high possibility that entirely new services or products turn out to be ones that fail to reflect market needs. In other words, when the DMB

Table 3. WiBro vs. DMB

		Category	
		WiBro	DMB
Service Coverage/ Content Variety	Coverage	Initial stage: 7 major cities Thereafter: Nationwide Preferred reception locations: Car, bus, train	Terrestrial DMB: Seoul and metropolitan areas Satellite DMB: Nationwide Preferred reception locations: Car, bus, train
	Content Variety	Information, e-commerce, chatting and communication, multimedia services	Multimedia-centered services
Customer		Prefer information and shopping services	Prefer multimedia services
Receiving Device		PDA, notebook computer	Mobile phone, car-mounted devices
Price		30,000 won	7,640 won

service is introduced to the market as a complementary service, rather than a competing service, to other similar services, its ripple effect over the communications market will be stronger and more substantial. Accordingly, for the successful launch of DMB and WiBro, instead of forming a rival relationship with WiBro service, DMB must be seen as complementing the perceived shortcoming of WiBro, namely its weakness in multimedia content offering. For long-term interest of the two services, it is wise for them to position themselves as each other's companion services.

POLICY ISSUES

Monopoly Market

Due to the withdrawal of bid by KT, the satellite DMB market has been monopolized by SK Telecom-affiliated TU Media. However, in the case of terrestrial DMB, many experts are still debating whether monopoly market or free competition market is appropriate. To prevent large broadcasting companies from monopolizing the terrestrial DMB market, the Broadcasting Act proposed by the Korea Broadcasting Commission limits the number of multiplex to one per operator. By using one multiplex, broadcasting companies can operate one video, three audio, and one data channels. If they want to operate only one multiplex, they can operate up to two video channels. However, KBS (Korean Broadcasting System, www.kbs.co.kr), the nation's representative public broadcaster, plans to operate two multiplexes for retransmission of KBS 1 TV, KBS 2 TV, and EBS (Education Broadcasting System). Other private broadcasting companies, including MBC (www.mbc.co.kr) and SBS (www.sbs.co.kr), are strongly protesting KBS's plan, by saying that if KBS operates two multiplexes and others operate one multiplex, it will constitute an unfair preferential treatment. Industry insiders are expressing apprehension as to the possibility of this discord leading to an outbreak of large controversy on an alleged inequity. The Korean Government is still investigating appropriate market structures of terrestrial DMB.

Retransmission of Terrestrial TV

In June 2004, at a public hearing, the Korea Broadcasting Commission disclosed a regulatory decision prohibiting the retransmission of terrestrial TV programs by satellite DMB, with the exception of KBS 1 TV and EBS. TU Media, a satellite DMB operator, was fiercely protesting against the prohibition of terrestrial TV retransmission. Numerous consumer surveys indicate that potential viewers are substantially less interested in subscribing to satellite DMB, if this service does not transmit terrestrial TV. Accordingly, with this decision by the Government, the market prospect of satellite DMB business as a whole will be put into question. Recently, Skylife, a Korean satellite broadcaster, finally received the authorization to retransmit terrestrial TV (MBC, SBS) starting next year. This restriction has been a true obstacle for satellite DMB providers' efforts to expand subscriber pools, and continues to limit and mitigate the outlook for this business area. Because the Korean Government is trying to prevent satellite DMB market from becoming a monopoly, its decision will not change anytime soon.

On the other hand, if the retransmission of terrestrial TV by satellite DMB is permitted, it will cancel out the key competitive elements of terrestrial DMB. Accordingly, it is advisable that the Government, rather than making an unconditional lifting of the retransmission restriction, instead wait and see how the market plays out and adjust its policy accordingly, so that these two DMB services can develop a complementary relationship.

Channel Compositions

The 25MHz frequency band used by satellite DMB has a transmission capacity of 7Mbps, and it is sufficient for operating up to 13 video channels. As public interests in satellite DMB are concentrated on video contents rather than audio contents, video content transmission is a priority for satellite DMB providers. However, because the Korean government strongly believes that terrestrial DMB service is inferior to satellite DMB, it supports terrestrial DMB and imposes many restrictions on satellite DMB. Given that situation, if the relationship between satellite DMB and terrestrial DMB turns out to be competitive rather than complementary, the restrictions on satellite DMB in the number of video channels allowed would be unfair and inappropriate. The overall DMB service market will be better served by loosening regulatory, directly geared toward stimulating terrestrial DMB business, rather than burdening the competing services with further restrictions such as a video channel restriction for satellite DMB.

CONCLUSIONS

This chapter reviews DMB technology, its business models, its market structures, and its policies. In particular, it explores business opportunities around DMB services and identifies major issues that must be solved to launch DMB services successfully. While the convergence of broadcasting and telecommunications is still in its early stages, it is nevertheless useful to draw a few preliminary conclusions from this survey in order to forecast trends in the worldwide telecommunication market, as well as the Korean telecommunication market.

In 1995–1997, many European countries, such as the UK, Sweden, France, and Germany, introduced DAB being similar to DMB into their markets. However, their markets have not expanded quickly. Experts point out that this market failure is caused by inability of existing terrestrial broadcasting companies in marketing and new service developments, and their conservative investments. Because telecommunication companies that have ample funds and are experienced in aggressive investment and marketing, play important roles in the DMB business in Korea, they are expected to overcome the problems encountered in European countries. The future of DMB in Korea is unpredictable, as it introduces a range of interrelated political, economic, and technical challenges. Particularly, the repeated failures in establishing a regulatory framework for DMB and ill-defined roles of players in the DMB industry might interfere the diffusion of DMB in the Korean market. As the convergence of broadcasting and telecommunications makes progress, proper modifications of existing regulatory frameworks should be made in order to guarantee success of DMB service in Korea.

Section 7

Critical Issues

This section addresses conceptual and theoretical issues related to the field of multimedia technologies, which include quality of service issues in multimedia transmission and the numerous approaches adopted by researchers that aid in making multimedia technologies more effective. Within these chapters, the reader is presented with analysis of the most current and relevant conceptual inquires within this growing field of study. Particular chapters address methodologies for the organization of multimedia objects and the relationship between cognition and multimedia. Overall, contributions within this section ask unique, often theoretical questions related to the study of multimedia technologies and, more often than not, conclude that solutions are both numerous and contradictory.

INTRODUCTION

The advent of 3G mobile communication networks has caused the fading of the classical boundaries between telecommunications, multimedia, and information technology sectors. The outcome of this convergence is the creation of a single platform that will allow ubiquitous access to the Internet, multimedia services, and interactive audiovisual services, and in addition (and most importantly) offering the required/appropriate perceived quality level at the end user's premises.

In this respect, multimedia services that distribute audiovisual content over 3G/4G mobile communication systems are expected to posses a major part of the bandwidth consumption, making necessary the use of video compression. Therefore, encoding techniques (e.g., MPEG, H-26x) will be applied which achieve high compression ratios by exploiting the redundancy in the spatiotemporal domain of the video content, but as a consequence produce image artifacts, which result in perceived quality degradation.

One of the 3G/4G visions is the provision of audiovisual content at various quality and price levels. There are many approaches to this issue, one being the perceived quality of service (PQoS) concept. The evaluation of the PQoS for audiovisual content will provide a user with a range of potential choices, covering the possibilities of

low-, medium-, or high-quality levels. Moreover the PQoS evaluation gives the service provider and network operator the capability to minimize the storage and network resources by allocating only the resources that are sufficient to maintain a specific level of user satisfaction.

The evaluation of the PQoS is a matter of post-encoding procedures. The methods and techniques that have been proposed in the bibliography mainly aim at:

- determining the encoding settings (i.e., resolution, frame rate, bit rate) that are required in order to carry out successfully a communication task of a multimedia application (i.e., videoconference); and
- evaluating the quality level of a media clip based on the detection of artifacts on the signal caused by the encoding process.

The scope of this article is to outline the existing procedures and methods for estimating the PQoS level of a multimedia service.

BACKGROUND

The advent of quality evaluation was based on applying pure mathematical/error-sensitive equations between the encoding and the original/uncompressed video signal. These primitive methods, although they provided a quantitative approach about the quality degradation of the encoded signal, do not provide reliable measurements of the perceived quality, because they miss the characteristics and sensitivities of the human visual system.

The most widely used primitive methods and quality metrics that are based on the error sensitivity framework are the peak signal to noise ratio (PSNR) and the mean square error (MSE):

$$\text{PSNR}=10\log_{10}\frac{L^2}{\text{MSE}}$$, *where L denotes the dynamic pixel value (i.e., equal to 255 for 8bits/pixel monotonic signal)* (1)

$$\text{MSE}=\frac{1}{N}\sum_{i=1}^{N}(x_i-y_i)^2$$, *where N denotes the total pixels and* x_i/y_i *the* i^{th} *pixel value in the original/distorted signal* (2)

Currently, the evaluation of the PQoS is a matter of objective and subjective evaluation procedures, each time taking place after the encoding process (post-encoding evaluation). Subjective picture/audio quality evaluation methods require a large amount of human resources, establishing it as a time-consuming process (e.g., large audiences evaluating video/audio sequences). Objective evaluation methods, on the other hand, can provide PQoS evaluation results faster, but require a large amount of machine resources and sophisticated apparatus configurations. Towards this, objective evaluation methods are based on and make use of multiple metrics, which are related to the content's artifacts (i.e., tilling, blurriness, error blocks, etc.) resulting during an encoding process.

These two categories of PQoS evaluation methods will be analyzed and discussed in the following sections.

SUBJECTIVE QUALITY EVALUATION METHODS

The subjective test methods, which have mainly been proposed by the International Telecommunications Union (ITU) and the Video Quality Experts Group (VQEG), involve an audience of people who watch a video sequence and score its quality, as perceived by them, under specific and controlled watching conditions. Afterwards, the statistical analysis of the collected data is used

for the evaluation of the perceived quality. The mean opinion score (MOS) is regarded as the most reliable subjective metric of quality measurement and has been applied on the most known subjective techniques.

Subjective test methods are described in ITU-R Rec. T.500-11 (2002) and ITU-T Rec. P.910 (1999), suggesting specific viewing conditions, criteria for the observer, test material selection, assessment procedure description, and statistical analysis methods. The BT.500-11 describes subjective methods that are specialized for television applications, whereas ITU-T Rec. P.910 is intended for multimedia applications.

The most known and most widely used subjective methods are:

- **Double Stimulus Impairment Scale (DSIS):** This method proposes that observers watch multiple references and degraded scene pairs, with the reference scene always shown first. Scoring is evaluated on an overall impression scale of impairment: imperceptible, perceptible but not annoying, slightly annoying, annoying, and very annoying. This scale is commonly known as the five-point scale (where 5 corresponds to "imperceptible" and 1 to "very annoying").
- **Single Stimulus (SS) Methods:** Multiple separate scenes are shown. There are two different SS approaches: SS with single view of test scenes and SS where the test scenes are repeated. Three different scoring methods are used:
  - **Adjectival:** The aforementioned five-grade impairment scale, however half-grades are allowed.
  - **Numerical:** An 11-grade numerical scale, useful if a reference is not available.
  - **Non-Categorical:** A continuous scale with no numbers or a large range, for example, 0-100.
- **Stimulus Comparison Method:** This methods exploits two well-matched screens, where the differences between scene pairs are scored in one of the two following scoring methods:
  - **Adjectival:** A seven-grade, +3 to -3 scale labeled: much better, better, slightly better, the same, slightly worse, worse, and much worse.
  - **Non-Categorical:** A continuous scale with no numbers or a relation number either in absolute terms or related to a standard pair.
- **Single Stimulus Continuous Quality Evaluation (SSCQE):** According to this method, the viewers watch a program of typically 20-30 minutes without any reference signal. The viewers, using a slider, continuously rate the instantaneously perceived quality using an adjectival scale from 'bad' to 'excellent', which corresponds to an equivalent numerical scale from 0 to 100.
- **Double Stimulus Continuous Quality Scale (DSCQS):** At DSCQS the viewers watch multiple pairs of quite short (i.e., 10 seconds) reference and test sequences. Each pair appears twice, with random order of the reference and the test sequence. The viewers/subjects are not aware of the reference/test order, and they are asked to rate each of the two separately on a continuous adjectival scale, ranging from 'bad' to 'excellent', which corresponds to an equivalent numerical scale from 0 to 100. This method is usually used for evaluating slight quality differences between the test and the reference sequence.

The aforementioned methods are described in the ITU-R Rec. T.500-11 document and are mainly intended for television signals. Based on slight modifications and adaptations of these methods, some other subjective evaluation methods (namely absolute category rating (ACR), degradation cat-

egory rating (DCR), etc.) for multimedia services are described in ITU-T Rec. P.910.

OBJECTIVE QUALITY EVALUATION METHODS

The preparation and execution of subjective tests is costly and time consuming, and its implementation today is limited to scientific purposes, especially at VQEG experiments.

For this reason, a lot of effort has recently been focused on developing cheaper, faster, and more easily applicable objective evaluation methods. These techniques successfully emulate the subjective quality assessment results, based on criteria and metrics that can be measured objectively. The objective methods are classified according to the availability of the original video signal, which is considered to be of high quality.

The majority of the proposed objective methods in the literature require the undistorted source video sequence as a reference entity in the quality evaluation process, and due to this are characterized as full reference methods. These methods emulate characteristics of the human visual system (HVS) using contrast sensitivity functions (CSF), channel decomposition, error normalization, weighting, and finally Minkowski error pooling for combining the error measurements into single perceived quality estimation (Wang, Sheikh, & Bovik, 2003).

However it has been reported (VQEG, 2000; Wang, Bovik, & Lu 2002) that these complicated methods do not provide more accurate results than the simple mathematical measures (such as PSNR). Due to this some new full reference metrics that are based on the video structural distortion, and not on error measurement, have been proposed (Wang et al., 2003).

On the other hand, the fact that these methods require the original video signal as reference deprives their use in commercial video service applications, where the initial undistorted clips are not accessible. Moreover, even if the reference clip is available, then synchronization predicaments between the undistorted and the distorted signal (which may have experienced frame loss) make the implementation of the full reference methods difficult and impractical.

Due to these reasons, recent research has focused on developing methods that can evaluate the PQoS level based on metrics, which use only some extracted structural features from the original signal (Reduced Reference Methods—Guawan & Ghanbari, 2003) or do not require any reference video signal (No Reference Methods—Lu, Wang, Bovik, & Kouloheris, 2002).

However, due to the fact that the 3G/4G vision is the provision of audiovisual content at various quality and price levels (Seeling, Reisslein, & Kulapala, 2004), there is great need for developing methods and tools that will help service providers to predict quickly and easily the PQoS level of a media clip. These methods will enable the determination of the specific encoding parameters that will satisfy a certain quality level. All the previously mentioned post-encoding methods may require repeating tests in order to determine the encoding parameters that satisfy a specific level of user satisfaction. This procedure is time consuming, complex, and impractical for implementation on the 3G/4G multimedia mobile applications.

Towards this, recently research was performed in the field of pre-encoding estimation and prediction of the PQoS level of a multimedia service as a function of the selected resolution and the encoding bit rate (Koumaras, Kourtis, & Martakos, 2005; Koumaras et al., 2004). These methods provide fast and quantified estimation of the PQoS, taking into account the instant PQoS variation due to the spatial and temporal (S-T) activity within a given encoded sequence. Quantifying this variation by the mean PQoS (MPQoS) as a function of the video encoding rate and the picture resolution, it finally used the MPQoS as a metric for pre-encoding PQoS assessment based

on the fast estimation of the S-T activity level of a video signal.

FUTURE TRENDS

Simultaneously with the development of the aforementioned methods and techniques, research has been focused on developing methods that determine the adequate quality level for a specific multimedia application, taking under consideration not solely the visual estimations, but also a great number of parameters and metrics that depend on the task nature and the user emotional behavior and psychophysical characteristics (Mullin, Smallwood, Watson, & Wilson, 2001). For example, the classification of the task as foreground or background in correlation with its complexity (Buxton, 1995) is a parameter that differentiates the quality demands of a multimedia application. On the other hand, the emotional content of a multimedia communication task alters the required quality level of the specific communication service (Olson, 1994). Due to this, various parameters are measured in order to estimate the appropriate minimum quality level of a multimedia application. Such parameters are:

- the user characteristics (i.e., knowledge background, language background, familiarity with the task, age);
- the situation characteristics (i.e., geographical remoteness, simultaneous number of users, distribution of users);
- the user cost (i.e., heart rate, blood volume pulse); and
- the user behavior (i.e., eye tracking, head movement).

However, these methods still have some issues to solve on the technical, theoretical, and practical levels. A user that participates in such an assessment procedure is so wired (even on the head, he or she may wear the eye tracking equipment) that it causes uncomfortable feelings and affects his or natural behavior. Technical issues, such as the eye tracking loss and the manual calibration/correction by a human operator, affect the reliability of the methods in real-time environments (Mullin et al., 2001).

CONCLUSION

Multimedia applications, and especially encoded video services, are expected to play a major role in third-generation (3G) and beyond mobile communication systems. Given that future service providers are expected to provide video applications at various price and quality levels, quick and economically affordable methods for preparing/encoding the offering media at various qualities need to be developed. There are a number of approaches to this challenge, one being the use of the perceived quality of service concept. The evaluation of the PQoS for multimedia and audiovisual content that has variable bandwidth demands will provide a user with a range of choices covering the possibilities of low-, medium-, or high-quality connections, an indication of service availability and cost. This article outlines the various existing PQoS evaluation methods and comments on their efficiency.

These methods can be mainly categorized into two major classes: subjective and objective. The subjective test methods involve an audience of people who watch a video sequence and evaluate its quality, as perceived by them, under specific and controlled watching conditions. The objective methods successfully emulate the subjective quality assessment results, based on criteria and metrics that can be measured objectively. These objective methods are classified according to the availability of the original video signal to full reference, reduced reference, and no reference.

However, all the aforementioned post-encoding methods require repeating post-encoding tests in order to determine the encoding parameters that

satisfy a specific level of user satisfaction, making them time consuming, complex, and impractical for implementation on the 3G/4G multimedia mobile applications. Due to this, lately some new pre-encoding evaluation methods have been proposed that are capable of estimating/predicting the PQoS level of a multimedia service based on the selected resolution, bit rate, and content activity. These methods quickly provide accurate estimations of PQoS level, alleviating the time and resource requirements that the traditional objective methods consume.

KEY TERMS

Bit Rate: A data rate expressed in bits per second. In video encoding the bit rate can be *constant*, which means that it retains a specific value for the whole encoding process, or *variable*, which means that it fluctuates around a specific value according to the content of the video signal.

Double Stimulus Continuous Quality Scale (DSCQS): A subjective evaluation method according to which the viewers watch multiple pairs of quite short (i.e., 10 seconds) reference and test sequences. Each pair appears twice, with random order of the reference and the test sequence.

Multimedia: The several different media types (e.g., text, audio, graphics, animation, video).

Objective Measurement of Perceived Quality: A category of assessment methods that evaluates the PQoS level based on metrics, which can be measured objectively.

Perceived Quality of Service (PQoS): The perceived quality level that a user experiences from a multimedia service.

Quality Degradation: The drop of the perceived quality to a lower level.

Single Stimulus Continuous Quality Evaluation (SSCQE): A subjective evaluation method according to which the viewers watch a program of typically 20-30 minutes, without the original reference shown, and score its quality.

Spatial-Temporal Activity Level: The dynamics of the video content, in respect to its spatial and temporal characteristics.

Wipro Technologies, India

INTRODUCTION

Providing support for QoS at the MAC layer in the IEEE 802.11 is one of the very active research areas. There are various methods that are being worked out to achieve QoS at MAC level. In this article we describe a proposed enhancement to the DCF (distributed coordination function) access method to provide QoS guarantee for wireless multimedia applications.

Wireless Multimedia Applications

With the advancement in wireless communication networks and portable computing technologies, the transport of real-time multimedia traffic over the wireless channel provides new services to the users. Transport is challenging due to the severe resource constraints of the wireless link and mobility. Key characteristics of multimedia-type application service are that they require different quality of service (QoS) guarantees.

The following characteristics of WLAN add to the design challenge:

- Low bandwidth of a few Mbps compared to wired LANs bandwidth of tens or hundreds Mbps.
- Communication range is limited to a few hundred feet.
- Noisy environment that leads to high probability of message loss.
- Co-existence with other potential WLANs competing on the same communication channel.

Figure 1. Block schematic of proposed system at AP

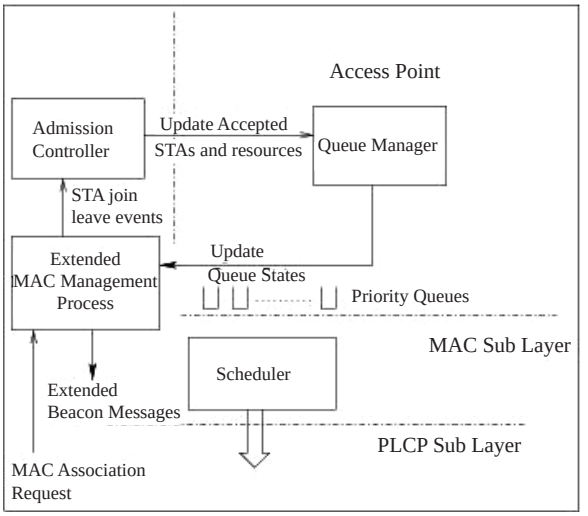

Figure 2. Block schematic of proposed system at mobile station

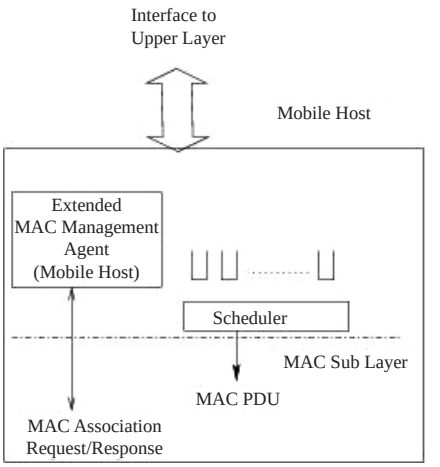


Successful launching of multimedia applications requires satisfying the application's QoS requirements.

The main metrics (or constraints) mentioned in such guidelines and that eventually influence the MAC design are: time delay, time delay variation and data rate. We develop a scheme to provide guaranteed data rate for different applications in WLAN environment.

PROPOSED ENHANCEMENT OF DCF TO PROVIDE QoS

The proposed enhancement is developed as a modular system, which integrates with DCF MAC of 802.11b wireless LAN.

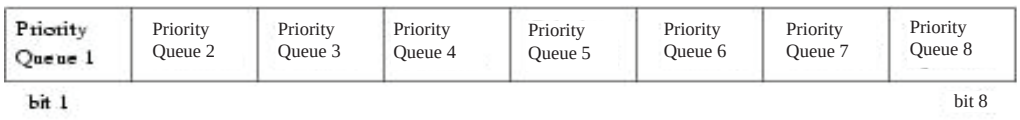
Salient Features of the Modular System

- Provides throughput guarantee for traffic flow between a pair of mobile stations.
- Works in distributed mode.
- Provides MAC level admission control for traffic flow.
- Applications on the mobile stations can send resource reservations request for each call (session).
- Works with backward compatibility, on hosts that do not support QoS enhancements.

Based on the basic principle of DCF access mode, each mobile station transmits data independent of other mobile station. Also, the AP (access point) has no role to play during the data transmission. Under this scenario, the throughput control (and guarantee) has to be achieved in a distributed manner.

One has to restrain a station from accessing the medium if there are other stations in the BSS that has requested for higher resource. If there is no such other station, the station is allowed to access the medium. We propose to use eight different priority flows. The queue manager at mobile stations maintains queues for these flows. Also, the state of these queues (if there are applications that are using this flow) is synchronized across all

Figure 3. Queue state field



Bit = 1 Queue is active
Bit = 0 Queue is inactive

Algorithm 1. Call admission controller algorithm

```
Begin
        for ( i = Min_Priority;i <= Max_Priority; i++ )
                do
                        if ( Requested_Tput + Current_Tput[i] <= Max_Tput[i] )
                                then
                                        goto accept_call
                                else
                                        continue
                        endif
                done
        Call RejectCall() /* No priority flow could fit this call */
        goto end

        accept_call:
                Current_Tput[i] = Current_Tput[i] + Request_Tput
                Call AcceptCall()
End
```

the mobile station via the beacon messages sent by AP. The scheduler transmits the packets from these priority queues using a priority algorithm. The admission controller admits a call to particular flow, if the acceptance of call to the flow do not over-shoot the throughput for that flow.

ARCHITECTURE OF THE MODULAR SYSTEM

The block schematics of the proposed system are given in Figures 1 and 2, for AP and mobile station respectively. The system has four major components:

1. Extended MAC management process
2. Admission controller
3. Queue manager
4. Scheduler

The detailed functioning of each of the components is explained in the following subsections.

Enhanced MAC Management Process

To signal the QoS messages, we propose an extension to MAC layer management messages to carry the resource request and responses.

To signal mobile host resource requirements to AP, we propose extension to the existing MAC management frames. This approach does

Algorithm 2. Scheduling packets

```
begin
        r  = rand()    /* r[0,1] */
        CurrentProb   0
        for(i=1 to N) /* N is number of active flows */
                do
                        if (r < CurrentProb)
                                Call TransmitPacket(i)
                        else
                                CurrentProb  = CurrentProb+NormPriority[i]
                        endif
                done
end
```

not need any changes in the core MAC layer. The SME (station management entity), which is normally residing in a separate management plane, needs modifications, which can be easily incorporated.

We incorporate enhanced MAC management with two segments.

MAC Management Process at AP

Apart from receiving and transmitting extended management frames to signal QoS, here the AP also broadcasts the queue states as an extension to beacon message.

MAC Management agent at Mobile Host

Apart from normal functionalities, the agent also receives the extended beacon message with queue states and passes this information to QM.

Management Message Modified

The beacon message is extended to include the queue states in a bit mask format. The queue state is an eight-bit field with each field representing a priority queue state. The queue is considered active if the bit is set, else inactive.

Admission Controller

The admission controller gets triggered by the extended MAC management process. The admission controller is a parameter based admission controller. However the decision process is modified to suit the distributed nature of DCF functionalities. While working in DCF mode each mobile station transmits/receives PDUs independent of AP and independent of other mobile stations. However the queue manager and scheduler as designed such that each station (while being completely independent) will transmit the PDUs at certain priority class. In order for the admission controller to admit a call, it needs to identify the maximum available throughput for a particular flow.

Based on [3] and [4] maximum achievable throughput per priority class is estimated as follows.

$$\text{Max Tput}[i] = \frac{P(\text{successful tx} \mid \text{flow} = i) * \text{Data pay load size}}{P(\text{collision}) * \text{Dur}_{\text{collision}} + P(\text{slot is idle}) * \text{aSlotTime} + P(\text{successful tx}) * \text{Dur}_{\text{success}}} \quad (1)$$

where $\text{Dur}_{\text{success}}$ is time duration for successful transmission of PDU, $\text{Dur}_{\text{collision}}$ is collision duration and aSlotTime is duration of one slot interval.

When a new call request arrives, the call is tried to fit in a flow of highest priority. By doing so, if the call requested throughput is achieved and existing calls are not disturbed, the call is accepted, or else the priority is decreased till the call is acceptable, if the call is not acceptable beyond least priority, the call is rejected. The admission control algorithm is described as follows.

Queue Manager

The main functionality of the queue manager is to synchronize the queue states across all mobile stations. Due to lack of any centralized coordinator, the queue manager synchronizes the states using broadcast messages. The queue manager at the AP broadcasts the states of queues to all the mobile stations in the BSS using extension to Beacon frames.

A queue for a particular flow is active if there are any calls in that flow, otherwise the queue is inactive. The queue states are broadcasted using bit masks in the extended beacon message, with each bit representing a flow. If the bit is set to 1, the queue for that flow is active; otherwise the queue is inactive. The queue manager module on station receives these broadcast messages and updates the queue state.

When all the stations have exchanged the states of the queue, each of the mobile stations would have synchronized queue states. Thus all the stations in the BSS will have a queue at particular priority level as active.

Scheduler

The scheduler's job to pick a packet from the priority flow queue and schedule them for transmission. The scheduler picks the packet from active queues. Irrespective of the fact the queue has data or not, the PacketTransmit function is called by the scheduler. The scheduler picks up the packet randomly from any of the active queues only. Now the probability to choose a queue is equal to normalized value of the priority of the queue. We define the normalized priority P_n as

$$P_{ni} = \frac{P_i}{\sum_K P_k} \tag{2}$$

where P_i is the priority of i^{th} queue.

We have assumed equal sized packets in all queues. For non-equal packet sizes the normalized priority would become:

$$P_{ni} = \frac{\frac{P_i}{S_i}}{\sum_k \frac{P_k}{S_k}} \tag{3}$$

where S_k is the size of k_{th} packet.

Each of the active queues is arranged in the ascending order of the priority. The scheduler selects the queue to be scheduled, and send the packet for transmission. The scheduling algorithm is described in Algorithm 2.

Packet Transmission Process

The PacketTransmit function checks for the packet and hands over the packet to MAC layer if the queue has data.

If the queue is empty, no packet is passed to the MAC function; however the packet transmission will back-off for other stations to transmit. A timer call back for a duration that represents the time taken by an average-sized packet is registered. This will provide opportunity for other stations with the packet in the same priority level queue to transmit the packet on to the medium.

The MAC will perform DCF access method to access the medium and make transmission. If the packet could not be transmitted due to wireless medium loss or collusion, the packet is retransmitted by the MAC layer, the scheduling is not changed due to retransmission. The packet transmission algorithm is described in Algorithm 3.

Table 1. Simulation parameters

Data Rate	11 Mbps
RTS Threshold	3000
Physical Layer Frequency	2457e+6
Transmission Power	31 mW
Receiver Threshold	1.15209e-10
Radio Propagation Model	TwoRayGround
LongRetryLimit	2

FUNCTIONING OF THE MODULAR SYSTEM

The functions of modular system are to gather the QoS requirements from the mobile stations and schedule their applications as per the specified QoS.

The functioning of the system is explained by considering the following cases.

Case 1. When New Mobile Station Enters the BSS with New Application

When a new station enters the BSS, the station joins the BSS using normal association procedure (as per IEEE802.11 standard). The AP instantiates a MAC management agent. The agent is migrated to the mobile host. The station uses the "Extended MAC Management Agent" to signal the resource requirements for new application. The AP receives the resource request, and passes on the QoS parameters to admission controller. The admission controller examines the resource requests, applies the admission control algorithm and accepts/rejects the request. The accept/reject response is conveyed back to the mobile station via the "Extended MAC Management process" module and updates the queue states in the QM. The QM updates the queue states for each of the flows, and sends them to the mobile stations as an extension to beacon message.

Figure 4. Throughput plot for mobile station with CBR traffic under DCF mode

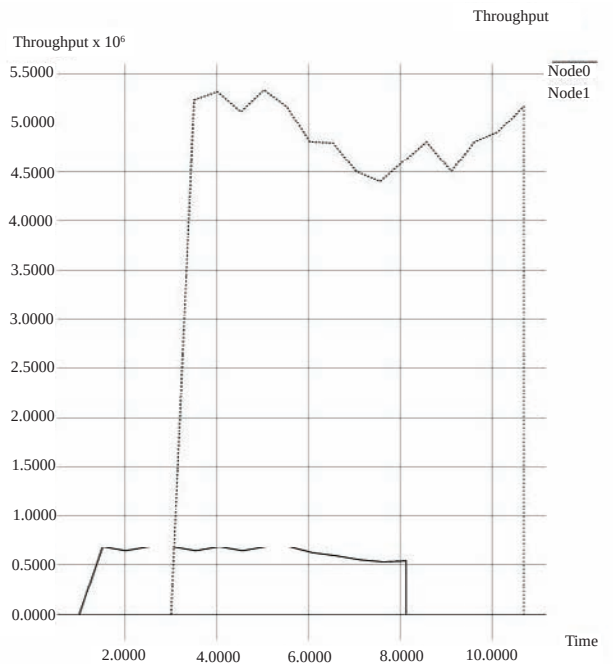


Figure 5. Throughput plot for mobile station with VBR traffic under DCF mode

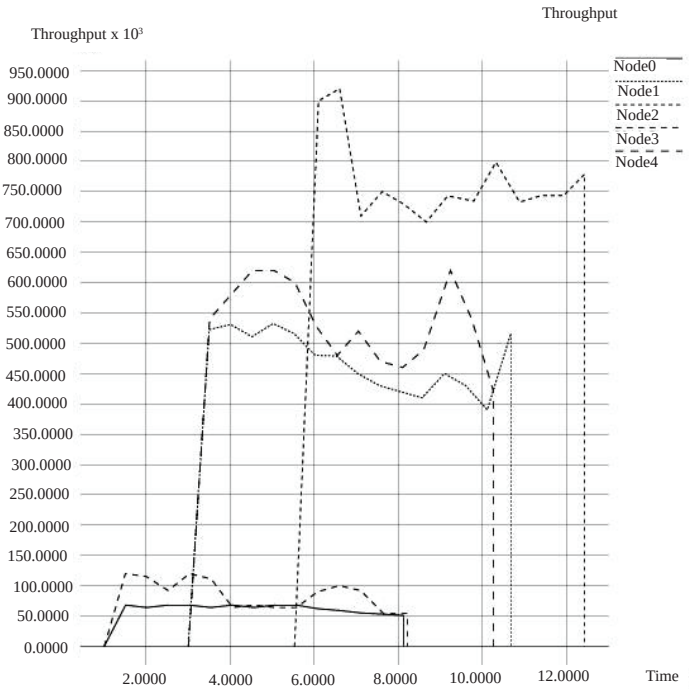

Figure 6. Normalized throughput for proposed scheme and standard DCF mod

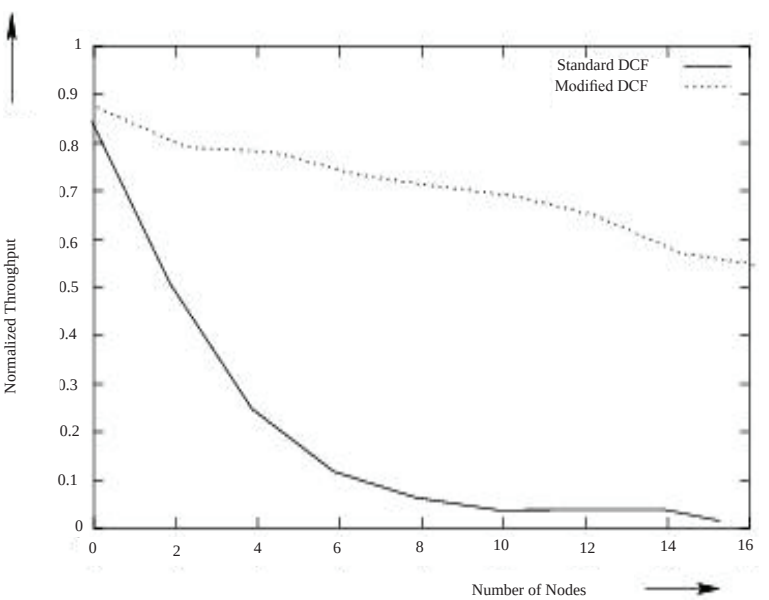

Upon reception of the response for the call request, the mobile station can start sending traffic. The QM at the mobile station receives the queue states in the extended beacon message and updates local queue state. The scheduler the mobile station schedules the traffic using the queue state information.

Case 2. When a Mobile Station Leaves the BSS

When the mobile station is about leave the BSS, the station uses the enhanced MAC management process to signal the AP. The AP receives the station ID, and updates the QM and admission control to relinquish the resource used all application under this station and changes the queue state if required.

Case 3. When New Application Has to be Admitted

A mobile station is already associated with the AP, and may be running some applications or otherwise. Under this condition, the station and AP follow the normal steps (as in Case 1), as this is no different from Case 1.

Case 4. When Applications are Terminated at the Mobile Station

A mobile station stops the current application, but the station is still in the BSS. When the application is stopped, the station uses the enhanced MAC management process to signal the AP that the application has stopped. The AP follows steps in Case 2 to relinquish the resource and update queue state.

IMPLEMENTATION CONSIDERATION

The system has two components, that is to say, AP component and mobile station component.

- The AC is implemented at the centralized location, normally co-located with the AP.
- Extension to MAC management layer, QM and scheduler are implemented in both AP and mobile station.

AP Components Implementation

It is easier to enhance the AP to support functionalities such as CAC, QM and scheduler since there is relatively very few numbers of APs and also the APs are normally controlled by the service provider, who wishes to provide QoS in the BSS. The AC, QM and scheduler are implemented in high-level system language (C) and integrated into the AP software. The MLME functions on the AP are modified to understand the extensions in the MAC frames and pass the QoS parameters to the CAC. The receive (RX) and transmit (TX) functions on the AP are modified to call the QM and scheduler functions respectively.

Mobile Station Components Implementation

The station components are implemented as Java byte-code, and the agent is instantiated at the AP and migrated to the mobile station, as the mobile station gets associated with the AP. The extended MAC management agent, QM and scheduler are implemented in Java.

SIMULATION AND RESULTS

We have used ns-2 [7] as simulator to validate the proposed system. Ns are a discrete event simulator targeted at networking research. Ns provides substantial support for simulation of TCP, routing, and multicast protocols over wired and wireless (local and satellite) networks.

Simulation Setup and Procedure

Using ns-2, a sixteen-node network working in BSS and iBSS modes is setup. We have modified the MAC layer functionalities in ns-2 to support the proposed system.

In the simulated system, the mobile nodes communicate with each other and external world over the 802.11b 11MBPS channel. The transmission power of the mobile is chosen such that stations are not hidden from one another. If not stated otherwise, during the simulation neither RTS/CTS nor the fragmentation is used. For most of our simulation we have considered on-off traffic with exponential distribution, and log-normal distribution for the radio channel errors. We have done several experiments by considering traffic in both upstream and downstream direction. The allowed traffic has been classified as VBR (variable bit-rate) and CBR (constant bit-rate) with random arrivals. The duration of each experiment varies from 100 seconds to 1,000 seconds. The simulation parameters that are significant are listed in Table 1.

We have simulated the proposed systems as three individual units. We explain the simulation for each case with CBR and VBR traffics.

The DCF MAC functions at each station are modified according to the proposed scheme. Each of the mobile station generates traffic destined to other nodes with data packets of 1,500bytes, 1,000 bytes, 512 bytes and 64 bytes.

In our first experiment, we considered two nodes generating CBR traffic. Each node requested a throughput of 10\% and 90\% of the net throughput. In Figure 4, we have plotted the throughput vs. time for two nodes. It can be observed that both the stations get the allocated bandwidth. Also when the node0 application is terminated, the node1 uses up the excess bandwidth.

In the next experiment, we have considered BSS with five nodes admitted for scheduling. The nodes requested throughput requirements are at 50, 100, 500, 550, and 750 Kbps. In Figure 5, we have plotted the throughput versus time for all the five nodes. It can be observed from the plot, each of the nodes is scheduled to get the allocated bandwidth.

Comparison with the Standard DCF Scheme

Again we use the normalized throughput as a measure to compare the proposed DCF scheme against the standard DCF scheme.

We have plotted the normalized throughput for a node working proposed DCF mode (with CBR traffic) against standard DCF mode in Figure 6. With the proposed scheme, the mobile 6station is admitted to the BSS via admission controller and the scheduler schedules the allocated bandwidth for the station. Hence the normalized throughput stays close to one. With the standard DCF, the mobile stations share the bandwidth in uncontrolled manner. Thus, as the number of stations increases in the BSS, there is no control over the bandwidth usage.

SUMMARY

In this article we have proposed method of providing QoS in wireless LAN operating in DCF mode. Providing QoS guarantee in a distributed environment has to be a distributed approach due to the distributed nature of the DCF. The proposed method requires small changes (extensions) to the MAC management entity and scheduler function operating at each station above the MAC layer.

KEY TERMS

Access Point (AP): An entity in the wireless LAN that is normally connected to a wired backbone and coordinates the operation of wireless mobile stations that are operating in infrastructure mode.

Call Admission Controller (CAC): A set of functions and procedures that control the admission of new calls into the system predictable based on predefined set of rules.

Media Access Controller (MAC): A set of procedures that governs the access to the media in a multiple access system. DCF (distributed coordination function) and PCF (point coordination function) are two MAC functions defined in IEEE 802.11 standard for wireless LAN.

Quality of Service (QoS): The term quality of service defines of quantitative representation of network resources that affect the application performance.

Chapter 7.3
QoS Adaptation in Multimedia Multicast Conference Applications for E-Learning Services

Sérgio Deusdado
Instituto Politécnico de Bragança, Portugal

Paulo Carvalho
Universidade do Minho Braga, Portugal

ABSTRACT

The evolution of the World Wide Web service has incorporated new distributed multimedia conference applications, powering a new generation of e-learning development and allowing improved interactivity and prohuman relations. Groupware applications are increasingly representative in the Internet home applications market, however, the Quality of Service (QoS) provided by the network is still a limitation impairing their performance. Such applications have found, in multicast technology, an ally contributing for their efficient implementation and scalability. Additionally, considering QoS as a design goal at the application level becomes crucial for groupware development, enabling QoS productivity to applications. The applications' ability to adapt themselves dynamically according to the resources availability can be considered a quality factor.Tolerant real-time applications, such as video conferences, are in the frontline to benefit from QoS adaptation. However, not all include adaptive technology able to provide both end-system and network quality awareness. Adaptation, in these cases, can be achieved by introducing a multiplatform middleware layer responsible for tutoring the applications' resources (enabling adjudication or limitation) based on the available processing and networking capabilities. Congregating these technological contributions, an adaptive platform has been developed integrating public domain multicast tools, applied to a Web-based distance learning system. The system is user-centered (e-student), aiming at good pedagogical practices and proactive usability for multimedia and network

resources. The services provided, including QoS adapted interactive multimedia multicast conferences (MMC), are fully integrated and transparent to end-users. QoS adaptation, when treated systematically in tolerant real-time applications, denotes advantages in group scalability and QoS sustainability in heterogeneous and unpredictable environments such as the Internet.

INTRODUCTION

Technology has been a strong catalyst for educational innovation and improvement, especially when the World Wide Web is involved. The next generation Internet needs technological support to accommodate promising new applications, such as interactive real-time multimedia distribution. Predictable bandwidth availability and capacity solvency imply QoS management to regulate resources in heterogeneous environments. Actually, increasing the network capacity through advanced network and media technology is not *per se* a ubiquitous and definitive solution to overcome the network capacity problem. Historically, the users have always managed to consume the entire system capacity soon after it was enlarged (Ferguson & Huston, 1998). IP Multicasting techniques (Deering, 1998; Kosiur, 1998; Moshin, Wong, & Bhutt, 2001; Thaler & Handley, 2000) are attractive solutions for this capacity shortage problem as bandwidth consumption is reduced when network resources are shared. On the other hand, the QoS support (Moshin, Wong, & Bhutt, 2001) should be, in a first instance, inherent to applications in order to integrate conveniently enhanced real-time multimedia applications in the present Internet, barely QoS aware and increasingly heterogeneous.

With the advent of wireless and mobile networks, heterogeneity is likely to subsist; envisioned applications should merge QoS adaptation and multicast in a proactive utilization of resources. Applications should be designed with adaptation in mind; they need to employ built-in mechanisms that allow them to probe the conditions of the network environment and alter their transmission characteristics accordingly (Miras, 2002). Self-adaptive applications, in the sense of proactive behavior for transmission of continuous media in multiparty applications, are a well-accepted solution due to the correct integration of new services in today's Internet (Deusdado, 2002; Li, Xu, Naharstedt, & Liu, 1998).

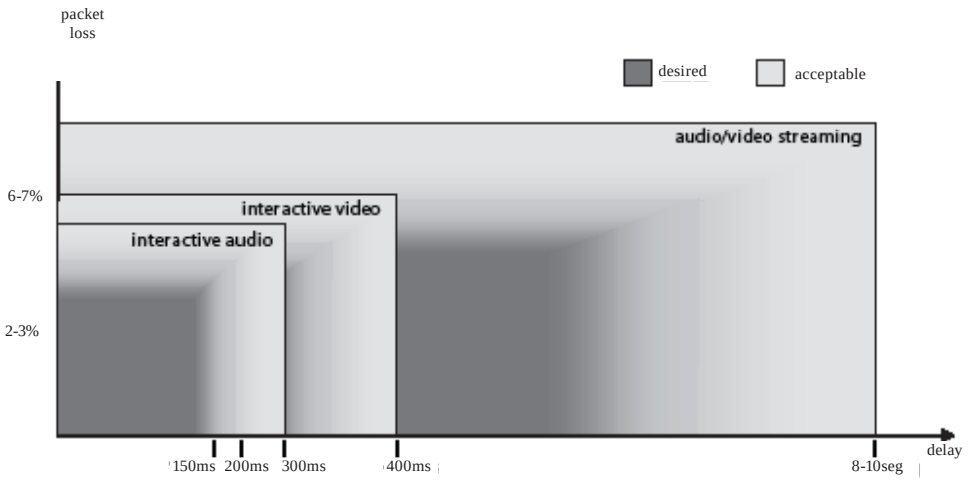
E-learning, as a component of flexible learning, encompasses a wide set of applications and processes which use available electronic media to deliver vocational education and training. It includes computer-based learning, Web-based learning, virtual classrooms and digital collaboration (Eklund, Kay, & Lunch, 2003). Our work aims to integrate interactive multimedia e-learning applications in a proactive fashion taking into account the available network resources and QoS sustainability. In this way, our motivation is to offer improved learning experience based on ultimate technology with QoS warranties.

The system architecture proposed in this article includes an adaptive module based on Java applets and embedded Javascript, responsible for assessing the existing operating conditions, by collecting metrics reflecting the client's end-system performance (e-student's host), the current network conditions and relevant multicast group characteristics. The collected data are subsequently computed weighting parameters such as the available bandwidth at the client side, the round-trip time between the client and the e-learning server, the client's current CPU load and free memory. The obtained results are used for proper multicast applications scheduling and parameterization in a transparent way.

MOTIVATIONS

Basically, e-learning services are used to promote connections between people (e-students)

Figure 1. QoS tolerance for generic audio and video applications (Miras, 2002)



and training resources (Steeples & Jones, 2002). E-learning research is wide and growing in importance, especially in higher education. Several institutions are developing interactive Web-based learning systems, integrating rich media streaming which may compromise network performance. The design of e-learning systems should consider QoS as mandatory for successful learning experiences, selecting the appropriate technologies and applications, and regulating proactively the information and communications technology (ICT) resources utilization (Allison, Ruddle, McKechan & Michaelson, 2001).

The Multicast Backbone (MBone) is a network overlaying the global Internet designed to support multipoint applications. MBone tools comprise a collection of audio, video and whiteboard applications that use Internet multicast protocols to enable multiway communications (point-to-multipoint and multipoint-to-multipoint), satisfying most of the needs of group communication, such as e-learning services. Using these applications by common e-students drives recurrently to poor QoS satisfaction due to the heterogeneity of resource conditions and the applications' inability to assess available conditions and adjust internal parameters before conference initiation. Without regulation, Real-time Transport Protocol (RTP) traffic floods the network capacity insensitively, forcing network congestion in certain cases or inhibiting better performance. A coherent behavior of an application without adaptation is difficult in today's Internet.

Public domain multicast applications used in this article, *vic* (McCanne & Jacobson, 1995), *rat* (Hardman, Kirstein, Sasse, Handley & Watson, 1995) and Java Media Framework (JMF) (JMF 2.0, 1999) were designed with no QoS "sensors," so the communication dynamics is not automatically interdependent of end-systems or network conditions. Effectively, such applications allow preparameterization to adjust critical parameters such as throughput, number of frames per second, video and audio encoding formats and so forth. Adaptation, in these cases, can be obtained by introducing a multiplatform middleware layer responsible for tutoring the applications' resources (adjudication or limitation) based on the available

processing and networking capabilities (Miras, 2002).

Common interactive real-time applications are fault-tolerant but suffer from QoS constraints; low-latency requirements and reliability are cumulative to achieve conference success. The diagram in Figure 1 attempts to illustrate the QoS tolerance, in terms of delay and packet loss, for generic interactive audio and video applications.

The main motivation of this article is to provide adaptive behavior to applications used on both sides of multimedia conferencing, focusing essentially on multicast members that initiate audio and/or video transmission. The underlying idea is to launch automatically MMC applications with proper audio and video codecs, bandwidth allocation inference and other parameters that affect sustainability and scalability during an e-learning session. Our emphasis is on the concept of "interactive e-learning services," relegating the concept of "e-learning course" to a secondary goal, which will be considered in future work.

Most prominent related work on friendly multimedia transmission over the Internet, based on a combination of system and network QoS feedback implementing equation-based adaptation is summarized in Bouras and Gkamas (2003) and Vandalore, Feng Jain, and Fahmy (2001).

SYSTEM'S ARCHITECTURE

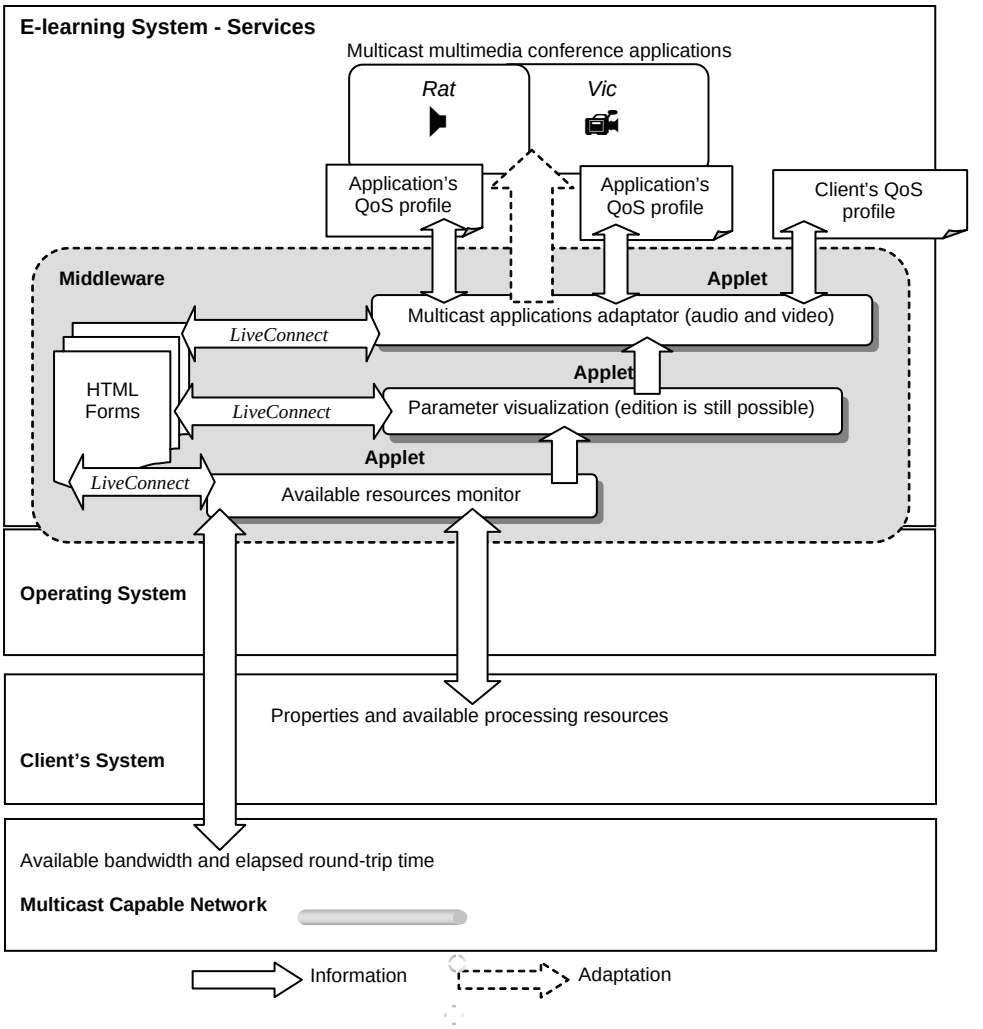
For multicast video distribution to heterogeneous users in an e-learning session, we assume that a class server (e-tutor's system) should be distributed and platform independent, considering inclusively multitutoring. Thus, a class server should connect to an e-learning server (Web server) and be submitted to adaptation as a regular new sender. The QoS requirements for the class server, operating in a centralized fashion, may justify the need of layered multicast (Johanson & Lie, 2002; Liu, Li & Zhang, 2004), enhancing the service's adaptation. However, this work aims at integrating e-students with heterogeneous equipment when they transmit audio and video to the group, as it happens in a conventional classroom. If a client (e-student) wants to interact and multicast video then the system's architecture will be integrated with fair adjustments attending both to the connection to the server (e-tutor) network and to the hardware processing capabilities. Client's adaptation should not depend on the other group members because they are transient, and consequently stability of transmissions could be very poor.

As the involved applications are characterized by an intensive use of host and network resources, the purpose of the middleware platform is to achieve by computation, on a scale of five differentiated modes, the proper integration of new multicasting members. Within this thematic, it means implementing an adaptive learners' participation in e-learning sessions by starting MMC applications transparently, with their functionality optimized for the current operating conditions.

To clarify these aspects Figure 2 illustrates the system architecture. As shown, three applets, operating sequentially and interdependently, are responsible for monitoring and assessing QoS conditions, inferring, announcing and/or editing computed adaptation parameters. The process culminates with the initiation of MMC applications, depending on the host and network profiles and covering eventual end-user explicit requirements.

Audio and video encoding formats, frame rate and other quality metrics may be chosen according to the resources' availability, providing coherent, friendly and fair participation in the network load balance. After monitoring sustainable network QoS with repeated measurements during approximately 15 seconds before media transmission, the Round-Trip Time (RTT) and bandwidth are calculated using a moving average. In addition, system's status variables, such as processor load, free memory, processor performance and so forth, are acquired, taking advantage of operating system facilities.

Figure 2. System's architecture



The system is multiplatform as the included applets differentiate the most popular operative systems (Windows and Unix), invoking appropriate inner services to obtain instant measures for the processor's load and free memory. The collected data constitutes another input to compute an adaptation index. Different compilations were produced for common browsers.

All of the adaptation process is transparent, however, regarding the experimental nature of this work, each phase allows interaction with the user, providing technical information or even accepting user preferences. To achieve this goal, applets and HTML forms interchange data using Sun's *Liveconnect* technology.

ADAPTIVE QoS FRAMEWORK

In the proposed framework, QoS management is performed individually for each new conference member and occurs before the transmission's start, such that MMC applications are launched adaptively facing the previous QoS sensing period

Table 1. vic and rat QoS parameters used to adjust applications' profile.

Vic	**-B** *kbps*	Sets the maximum bandwidth slider (kbps)
Vic	**-c** *dither*	On a color-mapped display, uses the algorithm indicated by dither (e.g., *ed*, *gray*, *od*, *quantize*) to convert to the available color palette
Vic	**-f** *format*	Indicates the video encoding format: *h261*, *h263*, *jpeg*, *nv*, ...
Vic	**-F** *fps*	Sets the maximum frame rate (fps)

Table 2. Set of parameters for different QoS adaptation modes

ADAPTATION MODE	MAXIMUM BANDWIDTH	FRAME RATE	VIDEO CODEC	COLOR	AUDIO CODEC
5	1 Mbps	30 fps	H.261	Yes	L16
4	512 kbps	25 fps	H.261	Yes	PCM
3	256 kbps	20 fps	H.261	Yes	DVI
2	128 kbps	15 fps	H.263	Yes	GSM
1	64 kbps	10 fps	H.263	No	LPC

conditions. QoS variability during the conference is not used to dynamically readapt the applications. If an e-student experiences lack of QoS while conferencing, the membership process should be restarted. Corroborating this practice, MMC applications, especially *vic*, are not stable enough. In fact, if some critical adjustments are made on-the-fly, the result is often the collapse of the application. Nevertheless, dynamic adaptation is currently a subject of study within group communication applications (Layaida & Hagimonte, 2002; Tusch, Böszörményi, Goldschmidt, Hellwagner & Schojer, 2004).

Considering the applications' specificity and type of traffic generated, adaptability only includes interactive audio *(rat*) and video *(vic)* applications and services. The heuristics regarding the choice of applications' QoS parameters emerged from experimental results and scientific references in this matter (Wu, Hou, Zhu, Zhang, & Peha, 2001). For instance, video conference users typically require better audio quality than video quality (Bolot, Crépin, & Garcia 1995). The success of video conferencing communication also depends on factors such as received frames per second, image quality, resolution, size and illumination.

For this work, the representative parameters of *vic* and *rat* used to modulate QoS are presented in Table 1.

The values for these parameters, deriving from a mathematical expression that generates an adaptation mode based on the sustainable QoS level, compose a set of adjusting directives determining the applications' behavior. Each adaptation mode indexes the respective set of adjustments, which will then be passed to the application. Since QoS scale varies from mode 1 to 5, when the obtained result is under or over this range it will be assigned to the nearest limit. Equation (1) determines the adaptation mode to be applied:

$$\mathbf{M = (int)\ (B/(RTT/2) + FM/P) *K} \qquad (1)$$

where [1],
M = QoS adaptation Mode (Table 2);
B = Bandwidth (kbps); **RTT** = Round-Trip Time (ms);
FM = Free Memory (MB); **P** = Processor load (%);
K = 1/50 - constant to scale the result (1 to 5).

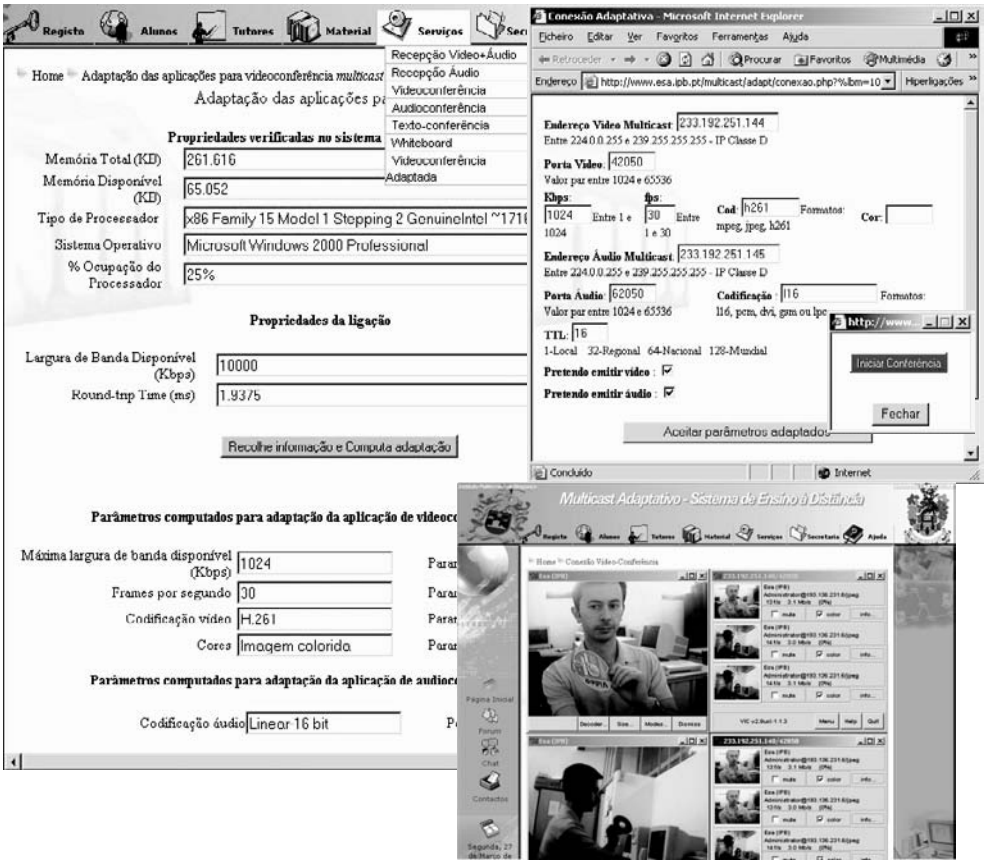
For *vic* (version 2.8), the video encoding formats H.261 (ITU-T H.261, 1993) and H.263 (ITU-T H.263, 1998) were those who revealed best performance for e-learning purposes, leading to low loss ratios and high reliability. H.263 is especially appropriate for low bandwidth environments.

E-LEARNING SERVICES AND FEATURES

The developed distance e-learning system presents numerous features providing distinct service levels, such as:

1. Virtual academy, Web-based with refined usability, integrating authentication and services for the e-learning community.
2. Registration, authentication and maintenance of educational agents.
3. Multicast sessions maintenance and scheduling.

Figure 3. E-learning system screenshots and MMC's adaptation HTML forms based on available QoS



4. Access to asynchronous material such as video on demand, slide presentations and other multimedia resources.
5. Interactive multimedia multicast conferences with QoS adaptation.
6. Other multicast tools for shared workspace.
7. Discussion spaces such as forum and multicast chat room.

This information system incorporates online databases structuring courses, students, tutors and sessions' data. These resources were developed using MySQL/PHP. A Web site congregating all developed application component prototypes is available at www.esa.ipb.pt/multicast.

Certain processes for assessing hardware performance require user's explicit authorization, allowing extended security privileges to applets in order to perform system's inspection and collecting substantial data used by subsequent applets of the control path. The security certificates used in this work are not provided by official entities, but generated by applet compilation tools for testing.

Although the adaptation process is totally transparent, effectively, the users may edit QoS parameters suggested by the system. If editing occurs, correctness and validation are assured by embedded *Javascript* code for parsing purposes.

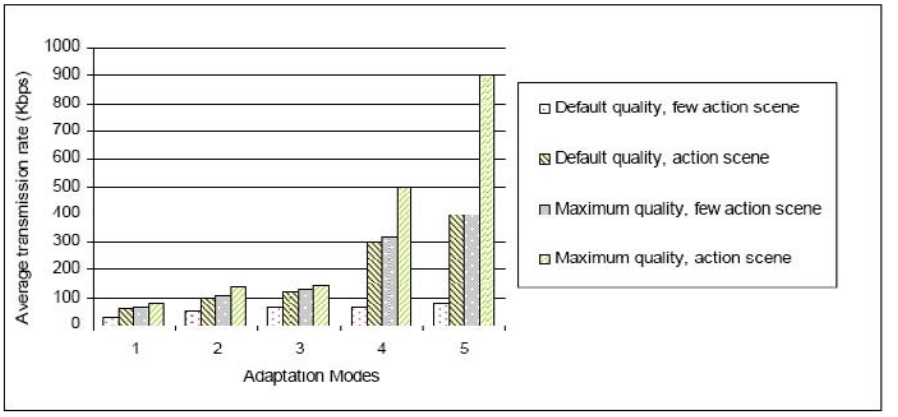

Figure 6 . Linear bandwidth distribution using applications' defaults, no adaptation is used.

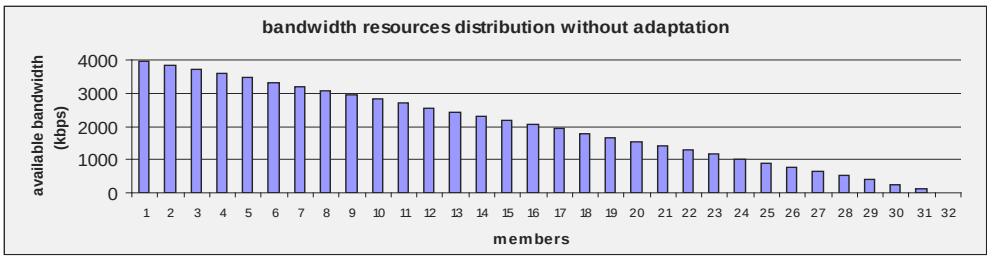

Figure 7. Increasing the number of active group members using adaptation to distribute network resources

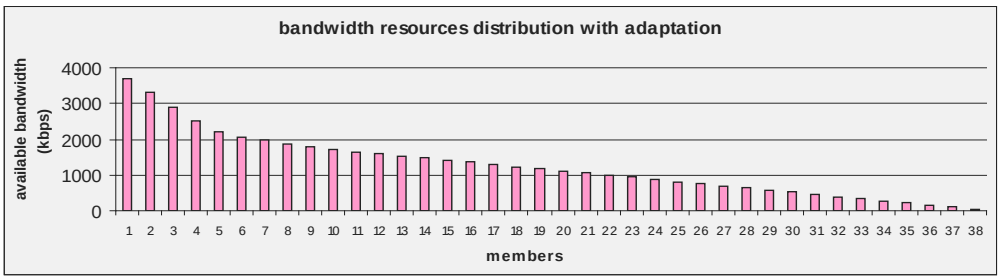

Figure 8. QoS mode adopted by the system facing the available resource conditions

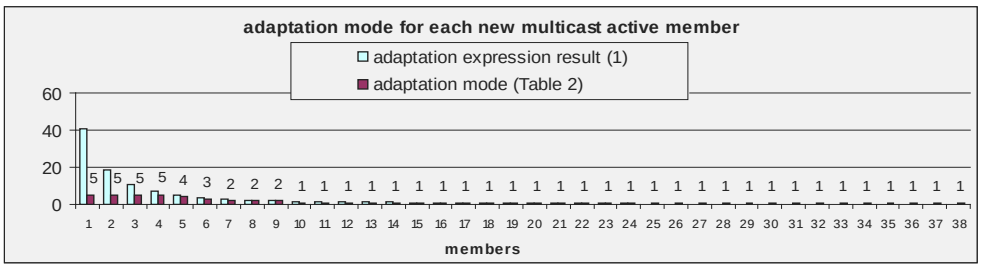

All MMC applications need to be previously installed and accessible through the command line interface, configuring the PATH environment variable properly. If we want to transmit audio or video the required equipment must also be ready. Gathering these basic requirements it is possible to participate in e-learning sessions, having adapted QoS in a transparent way, with great usability. Figure 3 integrates a system's screenshots, illustrating step by step, when a QoS adapted video conference is selected from the "Services" menu.

PERFORMANCE STUDY

Applications that use voice, video streams or multimedia must be carefully managed within

an IP network to preserve their operational integrity. Beyond routing improvements, QoS in a multimedia conference needs primarily to deal with several sources with different characteristics, shifting large amount of traffic competing for network capacity. MMC applications may easily absorb all network resources and the subjective quality sensed by users, would remain poor if the available resources are used indiscriminately. As mentioned earlier, the adaptation purpose, with e-learning in mind, was to integrate MMC applications with QoS conscience, preserving resources in order to maintain conference quality and improve scalability.

In order to test the framework, different scenarios were simulated and the corresponding resources' consumption verified considering the QoS limitations associated with each QoS mode defined in Table 2. For video conferencing, regarding e-learning purposes, it is widely accepted that reference values correspond to "Maximum quality, few action scene." Bandwidth consumption in *vic* default mode is 128 kbps. When adaptation is requested, the different adaptation modes use the values charted in Figure 4. For instance, the best quality mode consumes around 400 kbps, allowing better image and motion.

Different equipment was also tested in order to validate the rank of the defined adaptation modes. We observed that modern high performance equipment tends to be neutral; in this case adaptation will be influenced overall by network conditions, but with mobile computation in mind, PDAs and cellular phones, CPU performance should not be relegated.

The experimental results were obtained varying the number of new multicast members transmitting voice and video, considering that all the multicast group members are multimedia receivers and transmitters capable using Any Source Multicast (ASM) technology via *vic* and *rat* applications. Due to the limited number of multicast monitoring tools publicly available, we use embedded applications resource meters and the Multicast Monitor (www.multicastmonitor.com) to collect and handle the resulting data.

The e-learning system, more concretely the tested prototype showed good performance indicators that validate the architecture model proposed. Because video traffic is quantitatively more representative of resource consumption, it was analyzed preferentially. Figures 4 and 5 exhibit the levels of resource consumption for each QoS mode considered. Here, the overhead introduced by middleware to prepare applications is marginal as it occurs before transmission time.

QoS adaptation, when treated systematically in tolerant real-time applications, denotes advantages in group scalability and QoS sustainability in heterogeneous and unpredictable environments such as the Internet and Mbone. Figures 6, 7 and 8 illustrate a comparison between two simulated sessions, the first without QoS adaptation and the second including adaptation managed by the developed middleware layer. The results show that scalability increased, but equally important is the fact that applications may benefit from resource availability that does not occur when using the default applications configuration. When the available resources decrease, the system allocates them to critical parameters. For instance, while the frame rate should not be below 10 fps, the image quality may be poor or monochromatic if the contents are correctly perceived.

Limiting bandwidth to applications, not only with explicit parameterization but also choosing the right encoding format for e-learning sessions, allows efficient resource utilization and proactive usability, avoiding network overload and congestion. If the network load remains high, it is easier to recover if adaptation is used.

The experience with Mbone showed that e-learning groups tend to be small, usually less than 20 members. Effectively, e-learning communities, as in traditional training methods, need a tutor, who is mainly an educational agent and not necessarily a learning technologist. Indeed, questions related with communication technologies will

not constitute pedagogical limitation if intelligent QoS management autonomy is provided natively or by middleware to applications.

E-learning conferencing specificity requires appropriate video encoding formats able to achieve low loss ratio and fast recovery from congestion. We compared H.261 and Motion JPEG (ITU-JPEG, 1992) performance in experimental sessions, using a modest PC (PIII 0.7GHz - 256 MB RAM). The results were penalizing for

MJPEG, where loss was about 30%, in opposition to 1% for H.261.

CONCLUSION AND DISCUSSION

The goal of this article was, in one topic, to foster "ecological" practices in the Internet when using MMC's applications in e-learning services. The proposed system integrates public domain multicast applications for synchronous media communication, being supervised by a middleware based QoS management framework, intending to preserve the QoS of critical parameters for e-learning session's specificity.

As main contributions, this work:

1. Provides an integrated e-learning environment based on interactive multimedia services with proactive QoS;
2. Improves the usability of MMC applications; and
3. Allows the development of end-to-end QoS-aware multimedia conferences, coordinating resources from network, end-system processing equipment and applications.

Middleware adaptation is a solution that suits the present state of Internet and the requirements of new multimedia distributed applications. We use a middleware layer to manage QoS adaptation in interactive audio and video applications coordinating resource demand, monitoring and adjudication. Substantive results were obtained in group scalability, QoS sustainability and proactive resource utilization.

Comprising multiple sources (even unauthorized ones), ASM involves high complexity and may compromise the success of e-learning conferences. Future work includes the use of Source-Specific Multicast (SSM) (Holbrook & Cain, 2004) in order to overcome this limitation. The development of new multilayer video encoding formats could also increase the flexibility when using QoS adaptation. When cumulative layers are transmitted avoiding redundancy, using different SSM groups or channels, adaptation can be performed in a transparent way in order to achieve efficient resources utilization (Johanson & Lie, 2002; Liu, Li & Zhang, 2004).

Chapter 7.4
Quality of Service Issues in Mobile Multimedia Transmission

Nalin Sharda
Victoria University, Australia

ABSTRACT

The focus of this chapter is on the quality of service (QoS) aspects involved in transmitting multimedia information via mobile systems. Multimedia content and applications require sophisticated QoS protocols. These protocols need to manage throughput, delay, delay variance, error rate, and cost. How errors are handled in a multimedia session can have significant impact on the delay and delay variance. Coding and compression techniques also influence how the final presentation is transformed by the impediments encountered on a mobile network. Providing the user with the ability to negotiate between cost, quality, and temporal aspects is important, as this allows the user to strike a balance between these factors. In moving from 2G to 3G, and, over the next decade to 4G mobile networks, the ability to transmit multimedia information is going to improve constantly. Nonetheless, providers must develop viable economic models and user interfaces for providing differentiated QoS to the users.

INTRODUCTION

Transmission of multimedia information over mobile networks to portable devices, such as laptops, mobile phones, and PDAs (personal digital assistants), is leading to the development of new applications. However, successful transmission of multimedia information over mobile networks cannot be taken for granted. Understating the impediments to successful transmission of multimedia information is of paramount importance. This chapter focuses on multimedia applications that use mobile networks, and issues involved in the delivery of multimedia content with the desired quality of service (QoS). Current and future challenges in achieving successful mobile multimedia information transmission are also discussed.

Multimedia applications require more sophisticated QoS protocols than those for simple data transmission. The main parameters that underpin QoS are throughput, delay, delay variance, error rate, human perception of quality, and cost (Sharda, 1999). The interplay between these factors is rather complex, therefore, some simplifying assumptions must be made in developing

methodologies for delivering multimedia content with the desired QoS.

For the delivery of desired QoS, one of the most promising concepts developed over the last few years is that of resource reservation. This entails reserving resources such as bandwidth on interconnects, and buffer space and processing power on switching nodes.

Packet switching networks embody the idea of statistical time division multiplexing (STDM); that is, resources are allocated to a communication session based on the demands of the traffic. This leads to more efficient, and therefore, more economical usage of the resources. However, the need to allocate resources dynamically adds complexity to the communication system's operation and management. Mobile multimedia communications are further complicated due to their variable transmission quality, the need to keep track of end system location, restrictions placed due to limited battery life, reduced screen size, and the cost of the connection.

Over the last decade, some progress has been made in establishing mobile multimedia transmission systems. However, much research and development is still required before we can take it for granted that a multimedia application, such as videoconferencing, would run with the desired QoS over a mobile communication infrastructure on a hand-held device as we zoom down a freeway at high speed, and, all this at a reasonable cost.

The next section of this chapter presents the challenges introduced by the mobile multimedia content, applications, and communication systems. It begins with an overview of mobile multimedia systems, and then presents the implications of coding and compression techniques for transmitting multimedia. Requirements of various multimedia applications and their relationship to mobile communication systems are also presented.

The third section presents QoS issues in transmitting multimedia content over mobile systems. Fundamentals of QoS concepts and different QoS models are introduced, and a novel model for managing QoS in real time is presented.

The fourth section presents directions for future research, and the final section gives the conclusions.

MOBILE MULTIMEDIA SYSTEMS

Overview

This section presents an overview of coding methods used for various media types, multimedia applications, and current mobile communication systems. QoS issues related to each of these are also discussed.

Multimedia communication systems combine different types of media contents, such as text, audio, still images, and moving images, to achieve the overall objective of a communication session. Therefore, the network needs to provide a service which works well for all media types.

The requirements for successfully transmitting a particular media type depend upon its coding and compression techniques, and the application in which it is being used. Media content that must be transmitted live, or processed in real time, poses more stringent requirements. Consequently, live video conferencing is one of the most challenging multimedia applications.

The network infrastructure and the communications protocols used for transmission play a vital role in satisfying the demands of a given application. In general, multimedia transmission requires high bandwidth, low error rate, low delay, and very low delay variance. To date, we have not solved all of these challenges for even wired media. Fulfilling these requirements for achieving high-quality multimedia transmission over wireless connections is even more challenging.

The transition from the 2nd generation (2G) mobile systems to the 3rd generation (3G) mobile communication infrastructure presents new opportunities; however, still there are many chal-

lenging problems that need to be overcome. One of the key features missing in the current systems is the facility for the user to negotiate with the system and strike a compromise between the three key service aspects—quality, cost, and time—just as any market-oriented goods or services have to strike a balance between the quality, cost, and its delivery time.

Errors encountered in any transmission system can be either ignored, or detected and corrected. Errors can be ignored only if the received message is usable even with some errors. If errors in the received message are not acceptable, then these errors must be detected and corrected. Reverse error correction protocol requests retransmission of packets received with errors. This not only adds delay to the final reception of packets, it also adds delay jitter, as different packets encounter different delays. Forward error correction protocols include additional error correction bits, so that some of the errors can be corrected from the received data; this adds to the total data traffic. The choice of error handling method depends upon the type of data, its coding methodology, and the application.

Multimedia Content

By definition, a multimedia system combines different media types: text, audio, still and moving images. Each of these content types can be further categorised into sub-types. For example, still images can be bi-tonal, greyscale, or full-colour; furthermore, these can have continuous variation in tone—as in a photograph, or have sudden variation in the intensity—as in a printed page. A variety of techniques are used for digitally coding still images, depending upon the image type and application. Similarly, many text representation techniques and associated digital coding techniques are used. Audio and video are even more complex, as these are time varying quantities and involve continuous sampling over time. Errors and delays introduced at any stage of sampling, encoding, transmitting, and decoding of audio and video can lead to reduction in the quality of the final presentation.

Most multimedia content needs to be compressed to reduce the storage space and transmission bandwidth. Uncompressed multimedia content has in-built redundancy, and a few corrupted bits do not change the contents dramatically. Conversely, compressed media is compact, and has much less redundancy. Consequently, any errors during transmission affect compressed content more severely.

Mobile transmission systems are inherently more error-prone than wired transmission systems. The requirements for successfully transmitting a particular media type over a network depend not only on its coding and compression techniques, but on its application as well. However, all multimedia content is for human consumption, therefore, the criteria for acceptable quality of presentation ultimately depends upon human perception. For example, streamed video can accept a few seconds of delay, but live video conferencing becomes rather ineffective if the round-trip delay exceeds even a tenth of a second.

Text Coding

Despite the move towards graphical information, text remains a vital part of any multimedia presentation. One of the most enduring text codes is the American Standard Code for Information Interchange (ASCII). ASCII began its life as a 7-bit code designed for use with teletypes. Today, if someone talks of an ASCII document, they essentially refer to a text document with no formatting. Applications such as Notepad create ASCII text, and word processors can save a file as "text only". Extended ASCII codes were designed for computers to be able to handle additional characters from other languages. It took some time to get a single standard for these additional characters, and there are a few Extended ASCII sets.

Unicode provides a text code that is independent of platform, program, or language. In Unicode, a unique 16-bit number is reserved for every character. The Unicode standard aims to provide a universal repertoire with logical ordering that is efficient. The latest version of Unicode Standard is Unicode 4.0.1, and supports around a hundred international scripts.

ASCII and Unicode have been used extensively over wire-line communication systems, and can be used over wireless media as well. In general, transmission of text codes does not require high bandwidth or stringent limits on delay and delay variance. Hence maintaining QoS in transmitting text is often not much of a problem. Nonetheless, a new code set was designed for sending short text messages over mobile systems.

Short message service (SMS) uses a 7-bit code set that enables one to send and receive text messages of up to 160 characters on mobile phones. Some 8-bit messages are used for sending smart messages (such as images and ring tones) and for changing protocol settings. For Unicode-based text messages, 16-bit codes of maximum 70 characters can be used. These are viewable by most phones, and some appear as a flash SMS, that is, appear on the screen immediately upon arrival, without pressing any button. The SMS code was originally developed for the 2G technology, and therefore works well with 2G as well as 3G systems. The only possible issue with respect to QoS can be errors; bandwidth, delay, and delay jitter do not impede the transmission of SMS messages.

Non-Textual Information

The standard developed to transmit multimedia information over the Internet is the multipurpose Internet mail extensions (MIME). This standard was developed by the Internet Engineering Task Force (IETF) to support the transmission of mixed-media messages across TCP/IP networks. This also became the standard for transmitting foreign language text which the ASCII code could not represent.

Multimedia messaging service (MMS) provides the ability to send messages that combine text, sounds, images, and video over wireless networks. This requires handsets that are MMS capable. MMS is an open wireless standard specified by the WAP (wireless application protocol) forum—which has now been consolidated into the Open Mobile Alliance (OMA). In the WAP protocol, a notification message triggers the receiving terminal to start retrieving the message automatically using the WAP GET command. This retrieval may be modified by applying filters defined by the user. The content that can be transmitted with the WAP protocol can use a variety of media types and encoding standards.

Audio Coding

The basic technique for digitising analog audio signals is called pulse code modulation (PCM). In this technique, an analog audio signal is sampled at a rate double that of the maximum frequency that needs to be captured, and each sample is stored using 8-bit or 16-bit words.

Phone quality audio signals are sampled at 8,000 samples per second, and stored with 8-bit resolution; this generates 64 Kbps data rate. CD quality audio has two channels; it is sampled at 44,000 samples per second and saved with 16-bit resolution, giving a 1.4 Mbps data rate. A variety of compression techniques are used to reduce the bandwidth required to transmit audio signals. Compression becomes particularly important for CD quality stereo music, as the required 1.4 Mbps bandwidth is not economically available even in wire-line networks, much less so in wireless networks.

The MP3 (MPEG audio Layer 3) compression format has become one of the most widely used standards for transmitting high quality stereo audio. MP3 is one of three audio coding schemes associated with the MPEG video compression

standard. The MP3 standard provides the highest level of compression and uses perceptual audio coding and psychoacoustic compression to remove all redundant and irrelevant parts of a sound signal that the human ear does not hear. MP3 uses modified discrete cosine transform (MDCT) and improves the frequency resolution 18 times with respect to that of the MPEG audio Layer 2 coding scheme. It manages to reduce the CD bit rate of 1.4 Mbps down to 112-128 Kbps (a factor of 12) without sacrificing sound quality. Since MP3 files are small, they are easily transferred across the Internet, and are also suitable for transmission over wireless networks.

The next generation of MP3 standard is called mp3PRO. It is fully compatible with MP3, while halving the storage and bandwidth requirements. With this standard CD quality stereo can be transmitted at 64 Kbps. Furthermore, it can be used with digital rights management software, and can be ported transparently to any MP3-friendly application.

Advanced audio coding (AAC) is a wideband audio coding algorithm that exploits two main coding strategies to reduce the amount of data needed to encode high-quality digital audio. First, it removes signal components that are not important from a human perception point of view, and second, it eliminates redundancies in the coded audio signal. The MPEG-4 AAC standard incorporates MPEG-2 AAC, for data rates above 32 Kbps per channel. Additional techniques increase the effectiveness of the AAC technique at lower bit rates, and are able to add scalability and/or error resilience. (These techniques extend AAC into its MPEG-4 version: ISO/IEC 14496-3, Subpart 4.) The MPEG-4 aacPlus standard combines advanced audio coding techniques such as spectral band replication (SBR), and parametric stereo (PS). The SBR techniques deliver the same audio quality at half the bit rate, while the PS techniques (optimised for the 16-40 Kbps range) provide high audio quality at bit rates as low as 24 Kbps (Dietz & Meltzer, 2002).

The aacPlus codec family includes two versions. Version 2 of aacPlus is the high quality audio codec targeted for use in the 3GPP (3rd Generation Partnership Project). The aacPlus version 1 standard is adopted by 3GPP2 and ISMA (Internet Streaming Media Alliance) for digital video broadcasting (DVB).

The relationship between the aacPlus codec family members is shown in Figure 1 (Dietz & Meltzer, 2002). To compress the incoming stereo audio, the encoder extracts parametric representation of the stereo aspect of the audio. The stereo parametric information takes 2-3 Kbps and is transmitted along with the mono signal. Based on the parametric representation of the stereo information, the decoder regenerates the stereo signal from the received mono audio signal.

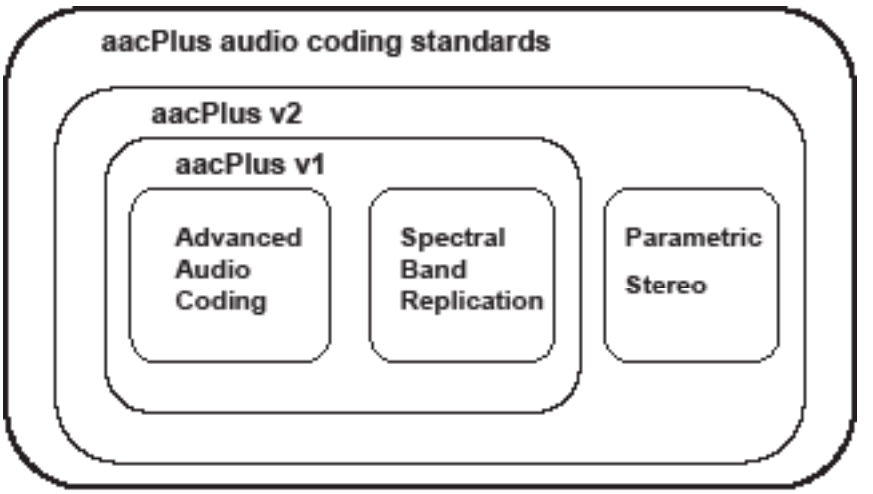
To be able to transmit high quality stereo audio, it is necessary to compress it to reduce the bandwidth, otherwise it may not be possible to obtain the desired QoS, especially over wireless networks. However, high level of compression makes the transmitted signal highly susceptible to errors, especially if the audio is being transmitted in real time. Any loss in the parametric information will severely degrade the quality of the reproduced stereo signal. Stereo is often used for music, and the slightest imperfection in music gets noticed by even non-experts.

Human ears are more sensitive to errors than human eyes. Human hearing faculties behave like differentiators, accentuating any variations, while human eyes behave like integrators, smoothening out variations (Sharda, 1999). Therefore, an audio stream should be given higher priority as compared to text or an image data stream.

Still Image Coding

Still image coding depends upon the type of image and its compression algorithm. Standards such as JPEG (Joint Photographic Experts Group), GIF (Graphics Interchange Format), and PNG (Portable Network Graphics) have dominated the field so

Figure 1. Relationship between aacPlus audio codecs v1 and v2 (Dietz & Meltzer, 2002)



far. JPEG is generally used for lossy compression of continuous tone images, such as photographs. GIF is a bitmap image format for pictures with 256 colours. PNG is a lossless bitmap image format. PNG improves upon the GIF format and is freely available.

The newer JPEG 2000 image compression standard uses a wavelet transform instead of the discrete cosine transform used in JPEG (Taubman & Marcellin, 2002). Therefore, JPEG 2000 can give higher compression ratio without generating the blocky and blurry artefacts introduced by the original JPEG standard. It also allows progressive downloads to extract various image resolutions, qualities, components, or spatial regions, without having to decompress the entire image. Distortion performance is also improved over the original JPEG standard, especially at low bit rates and at extremely high quality settings. JPEG 2000 is more error resilient as compared to the original JPEG standard (Secker & Taubman, 2004). This makes JPEG 2000 much better suited for applications requiring image transmission over wireless networks, as errors and delays introduce fewer observable artefacts in the displayed image.

Wireless networks experience higher error rates, and have lower bandwidth. Therefore, they are more severely challenged when transmitting digital images. Since the JPEG 2000 standard provides higher compression ratios, it is more suitable for the low bandwidth wireless networks; however, some additional issues need to be addressed (Santa-Cruz, Grosbois, & Ebrahimi, 2002). Issues such as error resilience over wireless networks are being addressed by the JPEG 2000 Wireless (JPWL) team. Their aim is to standardise tools and methods for efficient transmission of JPEG 2000 images over error-prone wireless networks. One of the techniques being developed by JPWL make the code stream more error resilient by adding redundancy, or by interleaving data (Dufaux & Nicholson, 2004). The decoder not only detects errors, but also corrects some, where possible. Another technique changes the sensitivity of different parts of the code stream to errors. More sensitive sections of the code stream are more heavily protected than the less sensitive sections. The third technique describes the locations of the remaining errors in the code stream;

the decoder then uses this information to exclude the corrupted parts of the code stream from the decoding process.

By standardising these techniques in JPWL, JPEG 2000 is being made more resilient to transmission errors, making it an ideal choice for the transmission of digital images and video over wireless media.

Moving Image Coding

Moving image coding can entail storing up to 20-30 image frames in every second. This demands very high bandwidth for high quality uncompressed video. Development of video coding standards that provide low resolution and low frame rate video suitable for transmission over networks began with the H.261 standard published by the ITU (International Telecom Union) in 1990, with data rates in multiples of 64 Kbps. The H.263 version provided a replacement for H.261 (in 1995) to work at all bit rates. It was further enhanced as H.263v2 (in 1998) and H.263v3 (in 2000). H.263 is similar to H.261, with improved performance and error recovery, and supports CIF,[1] QCIF, SQCIF, 4CIF, and 16CIF images. As these standards are designed for multiples of 64Kbps rates these are sometimes called px64 (where p can be 1-30). Originally these data rates were expected to suit ISDN (integrated services digital network) lines, nonetheless, these standards are useful in transmitting video over other wire-line and wireless networks also. H.263 is the baseline standard for the new 3G-324M standard, which targets the 3G wireless networks (Smith & Jabri, 2004).

Another option within the 3G-324M specification is the next generation video coding standard MPEG-4 AVC. It was approved in 2003 and called MPEG-4 AVC or ITU-T H.264, or simply advanced video coding (AVC).

MPEG-4 AVC doubles the compression efficiency of earlier standards for the same picture quality, which leads to 50% lower bandwidth (Navakitkanok & Aramvith, 2004). Therefore, it is far better than the earlier standards for wireless transmission. It offers improved resilience to transport errors, improved bit rate scalability, and stream switching for transmission over less reliable network infrastructure, such as wireless networks.

Motion JPEG 2000 (like Motion JPEG) can perform video compression applying only intra-frame compression. This makes Motion JPEG 2000 well suited for video transmission over wireless networks. It has been demonstrated that Motion JPEG 2000 outperforms MPEG-4 in terms of coding efficiency, error resilience, complexity, scalability, and coding delay (Tabesh, Bilgin, Krishnan, & Marcellin, 2005).

The JPWL work has taken into consideration the general principle underpinning networking protocols, with particular attention given to 3G networks (3GPP/3GPP2), wireless LANs (WLAN based on the IEEE 802.11 standards family), and Digital Radio Mondiale (DRM), making motion JPEG 2000 particularly suitable for wireless networks.

Multimedia Applications

Applications which have so far been bound to wire-line networks and desktop computers, now want to be let loose. The only option is to use wireless networks and portable devices. Areas for such mobile multimedia applications include both personal and business communications. E-learning, marketing, travel, and tourism are just a few of the burgeoning application areas that can make good use of mobile multimedia systems. Some of the potential killer applications based on the JPEG 2000 Wireless (JPWL) methods include video streaming and video conferencing (Liu & Choudary, 2004).

Mobile systems offer new opportunities and challenges as they become capable of transmitting multimedia information. Such applications need to transmit not only the core information, but also some associated meta-information. Most

electronic systems use multi-tier information transmission processes, which include: intimation of arrival (bell, ring, beep, and vibrate); abbreviated information (subject, caller ID); textual information (text message, SMS); multimedia information, and meta-information for layered retrieval of the information.

How a particular information type and associated meta-information is used depends upon the application, the user preference, user device, and the required QoS (Cheng & Shang, 2005).

Text Applications

Text is very useful for communication. It is often said that a picture is worth a thousand words; nonetheless, we should not forget that a few well chosen words can be worth scores of pictures. Additionally, text requires much lower bandwidth, and has greater certainty of meaning. It is more reliable in the face of transmission errors, especially if we use either reverse or forward error correction protocols.

Text is easy to transmit asynchronously or synchronously. One can send an SMS to a friend during work, without the fear of disturbing her in an import meeting. The receiver can reply in her own time, or the two can engage in a brief chat session to fix their evening rendezvous. The runaway success of SMS follows the predicate that "brevity is the soul of wit," as SMS allows succinct messages that convey the meaning quickly. Coded messages based on SMS have also become prevalent, further reducing the time taken to enter and read the message.

Some commonly used SMS codes include: *ATB—All the best; BRB—Be right back; GR8—Great; LUV—Love; PCM—Please call me; TTYL—Talk to you later; 2DAY—Today; and WER R U—Where are you?* SMS codes are also being used to download information to mobile phones, such as snow photos to check the condition on ski slopes.

In Japan, codes called Emoji have been developed. These are colourful, and often animated inline graphics used for mobile messaging. However, these are not standardised or interoperable between carriers. Emonji's are treated as characters, and each carrier has its own set.

In conclusion, text or text-like messages are, and will remain, an important aspect of mobile communications, especially because these are inexpensive, highly expressive, and are least problematic with respect to delivery with the desired QoS.

Audio Applications

Transmission of voice was the original motivation for developing the mobile communications technology. However, digital radio is also coming online, and integrating digital radio in mobile phones is in the offing. An Austrian company Livetunes has developed UMTS-enabled handset with digital radio. SIRIUS Satellite Radio can transmit commercial-free music and other audio entertainment to cars and homes. Mobile audio commercials over such digital radio channels allow advertisers to send audio commercials to their customers' mobile phone. The customer receives a phone call; upon answering the call, the audio commercial is played. It can include new offers, promotions, and announcements. To avoid spamming, companies have to provide their own subscriber database and the audio clip.

The QoS requirements for audio are different for bi-directional conversation than those for uni-directional digital radio transmission. For digital radio, buffering can be used to remove any delay jitter; however, excessive buffering can add unacceptable delay to conversational applications (Sharda, 1999).

Human hearing is very sensitive to any distortion in audio. For conversational audio, we can tolerate some errors, as long as the meaning of the spoken words is clear. If there is a problem in understanding the meaning, then the listener can

always ask the speaker to repeat what was said. This is like reverse error correction working at the highest communication layer, that is, the user layer. However, this cannot work for stereo music; as human hearing works like a differentiator, and any distortion gets accentuated. Furthermore, our hearing is capable of picking slightest variation between the two channels of stereo music. Therefore, QoS issues are very important when high quality stereo music is transmitted, but not so important for conversational audio.

Still Image Applications

Applications needing still image transmission can use multimedia messaging service (MMS). Examples of MMS based applications include: weather reports giving images, stock prices displayed as graphs, football goals displayed as a slide show, and many more. An extension of still image transmission is animated text messages. The main QoS factor that affects still images is delay. As delay jitter does not effect still image transmission, any errors can be overcome by using reverse error correction protocols. If such additional delays are not acceptable, then images can be displayed with errors. Uncompressed images can tolerate a high level of errors; however, the ability to tolerate errors reduces for compressed images. The original JPEG type compression techniques lead to blocky images when errors occur, as they use discrete cosine transform. However, JPEG 2000 compression standard overcomes this problem by using wavelet transform. Images compressed with JPEG 2000 degrade "gracefully" in face of errors. As wireless communication systems are inherently more error prone, image-based applications will benefit from the use of JPEG 2000 standard for their compression (Dufaux & Nicholson, 2004).

Content repurposing is also becoming important, so that the content creator can compile content only once, and the system can vary image size and resolution depending upon the display screen size and the communications channel bandwidth (Rokou & Rokos, 2004)

The aim of content repurposing is to push the content with the most appropriate resolution, so that it can be transmitted over the available network to meet the QoS goals. In general, this would imply pushing lower resolution images over wireless networks. However, with JPEG 2000 and JPWL, the system can push a rough image to begin with, which keeps improving as more data bits are transmitted.

Video Applications

Video phones are a natural extension of the current audio telephony. Wire-line based video phones were demonstrated decades ago, however, these never became popular. Mobile video telephony is likely to become popular once the cost of transmitting acceptable quality video becomes affordable. In the meanwhile, look-at-this (LAT) applications will generate demand for mobile Internet and 3G wireless networks, as these will create large amount of real-time mobile video. Some possible LAT application areas include:

a. **Retail:** Before purchasing an item, the consumer sends an image of the item to their partner for comment or approval.
b. **Real Estate:** An agent sends images of the building and its surrounding areas to the prospective customer.
c. **General Business:** A worker sends live video to colleague(s) at other location(s) while holding a voice conversation. This could be applied to developing new ideas; designing new products; repairing faulty equipment; maintaining, installing, or inspecting a system.

QoS is of great importance in video transmission. Video conferencing is the most challenging multimedia application for transmission over mobile systems. Much effort has gone in to migrating

from 2G networks to 3G networks to provide the desired QoS for video transmission. However, the cost of transmission is still high enough for it to be an impediment in its large-scale adoption.

Mobile Communication Systems

The desire to communicate over long distances has been an innate need for human beings since time immemorial. We can reflect that the earliest telecommunications systems devised by human beings were wireless systems, namely, smoke signals, semaphore flags, drums, and yodelling and so forth. Therefore, it is not surprising that electronic communications are also moving towards wireless systems.

Evolution of Telecommunications

Electric telecommunications began with the telegraph demonstrated by Morse in 1837 and the telephone developed by Bell in 1876. Marconi began his experiment with radio transmission in 1895. Automation of circuit switching systems began in 1919 with the Strowger exchange. The era of satellite communications dawned with the Telstar satellite in 1950. Saber became the first major data network in 1962.

Evolution of Mobile Systems

An early landmark in the development of wireless communications was the patent for the spread spectrum concept, proposed in 1941 by Hedy Lamarr. The first mobile telephone service was setup in St. Louis by AT&T as far back as 1946. Some theoretical breakthroughs also occurred around this time. In 1948, Claude Shannon published the Shannon-Hartley equation, and in 1949 Claude Shannon and Robert Pierce develop the underlying concepts for CDMA (code-division multiple access). In 1950, Sture Lauhrén made the world's first cellphone call, and by 1956, Swedish PTT Televerket operated a mobile telephone service. In 1969, the Nordic Mobile Telephone Group started a mobile service. CDMA was deployed for military systems in the 1970s. In 1973, Motorola vice presidents Marty Cooper and John Mitchell demonstrated the first public call from a handheld wireless phone.

Evolution of Digital Mobile Systems

First Global System for Mobile Communications (GSM) technology based networks were implemented by Radiolinja in Finland in 1991. In 1992, the Japanese Digital Cellular (JDC) system was introduced. By 1993, the IS-95 CDMA standard got finalised. First meetings of the 3GPP (3rd Generation Partnership Project) Technical Specification Group was held in December 1998. In 2000, Siemens demonstrated the world's first 3G/UMTS (3rd Generation Universal Mobile Telecommunications System) call over a TD-CDMA (time division-CDMA) network.

In 2000, commercial GPRS (general packet radio service) networks were launched. These networks supported data rates up to 115 Kbps, as compared to GSM systems with 9.6 Kbps data rates. In 2001 NTT (Nippon Telegraph & Telephone Corp.) produced commercial WCDMA (wide-band CDMA) 3G mobile network. In 2003, Ericsson demonstrated the transmission of IPv6 traffic over 3G UMTS using WCDMA technology.

Fixed Wireless vs. Mobile Communications

We need to distinguish between fixed wireless communication systems and mobile communication systems. A mobile communication system frees the end systems from the tyranny of being connected to a wall socket, and provides the ability to communicate anytime and anywhere. It allows the freedom to roam outside the home or the office.

Fixed wireless communication systems are local alternatives to wired communication systems. These do not provide mobility outside the home or the office, nonetheless, they provide a cost effective telecommunications connection for a given location with the ability to move around within a specified boundary.

For remote locations, satellite-based communication systems may be the only means of establishing a connection; however, these can be expensive. Satellite connections add about half a second round trip delay, making full-duplex audio or video connections rather difficult. While there is appreciable delay in a satellite connection, the delay variance is not very high, as the number of hops is fixed at two—transmitter to the satellite, and satellite to the transmitter. Error rates can be high on a satellite connection, especially burst errors—in case of atmospheric disturbances.

Universal Mobile Telecommunications System (UMTS)

Today, there are more than 60 3G/UMTS networks using WCDMA technology. Over 25 countries have adopted this technology, and there is a choice of over 100 terminal designs in Asia, Europe, and the U.S. The 3G mobile technologies identified by ITU for 3G/UMTS offer broadband capabilities to support a large number of voice and data customers, and offer much higher data rates at a lower incremental cost than the 2G technologies (Myers, 2004).

One of the issues driving the development and proliferation of 3G technologies is the recognition that there is a need for guaranteeing the QoS for multimedia traffic. Without guaranteed QoS, many applications fail to perform as per the users' expectations. Until the users are confident of getting the quality they need for running mobile multimedia applications effectively, they will not shift from their current mode of operation and adopt the new wireless networking technologies for multimedia information transmission.

QUALITY OF SERVICE IN MOBILE SYSTEMS

This section gives an overview of the various approaches being trailed for the provision of QoS in mobile networks. While much work has been done in providing QoS guarantees at the network infrastructure level, a holistic approach to providing end-to-end QoS has been missing to some extent. We begin by presenting a QoS model that focuses on the user, and develops a methodology for allowing the user to negotiate with the system to find a compromise between cost, quality, and temporal aspects.

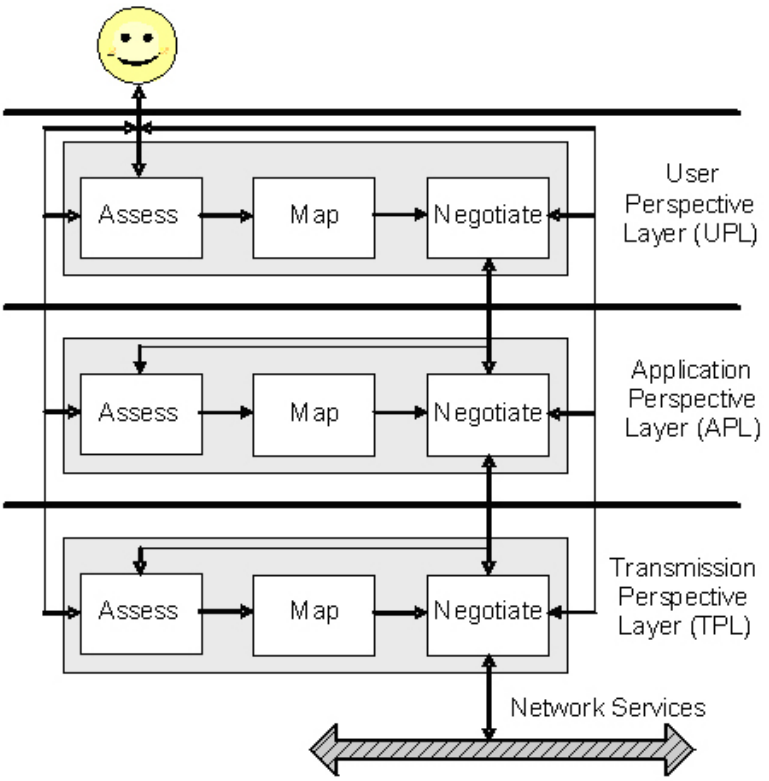
QoS Concepts and Models

The three layer quality of service (TRAQS) model shown in Figure 2 comprises three layers for QoS management in multimedia communications (Sharda & Georgievski, 2002). These three layers are: user perspective layer, application perspective layer, and transmission perspective layer. Each layer performs QoS processing for a set of QoS parameters that are related to the specific perspective. The main functions of the three perspective layers are:

- **User Perspective Layer (UPL)** interacts and performs QoS negotiations with the user and then transfer the QoS request to the APL.
- **Application Perspective Layer (APL)** first assesses the QoS request received from the UPL, and aims to satisfy the needs of the multimedia application by requesting the required services from the TPL.
- **Transmission Perspective Layer (TPL)** is responsible for negotiating with the network infrastructure to obtain appropriate communication services that can guarantee QoS.

Similarly, the various QoS protocols developed at the network infrastructure level need to be

Figure 2. Three layer QoS (TRAQS) model (Sharda, 1999)



able to communicate with the TPL to allow the user to specify the desired compromise between cost, quality, and temporal issues such as delay and jitter.

Quality, Cost, Temporal Triangle (QCTT)

In purchasing any goods or services one needs to find a compromise between three important factors: cost, quality, and time. While one would like to get the best quality at the least cost and in the shortest time, in practice, this is not possible. One must strike a compromise between these three factors. So far mobile communications systems have not come to grips with this reality. Future communication systems must provide users the ability to specify what quality and temporal aspects (such as delay and jitter) they want, and then systems should respond with the cost it would charge to provide that quality.

Only with a differentiated cost can the telecommunications service providers afford to deliver the required QoS. If the cost is too low, the network may be overwhelmed with traffic, and none of the users can then obtain the desired QoS. Over and above this, the network services provider may not be able to make profit. On the other hand, if the cost is too high, there will not be enough consumers using the service, once again making it difficult for the service provider to get return on investment. Whereas, by providing the user the ability to negotiate, the consumer and the service provider can both have a win-win situation; some

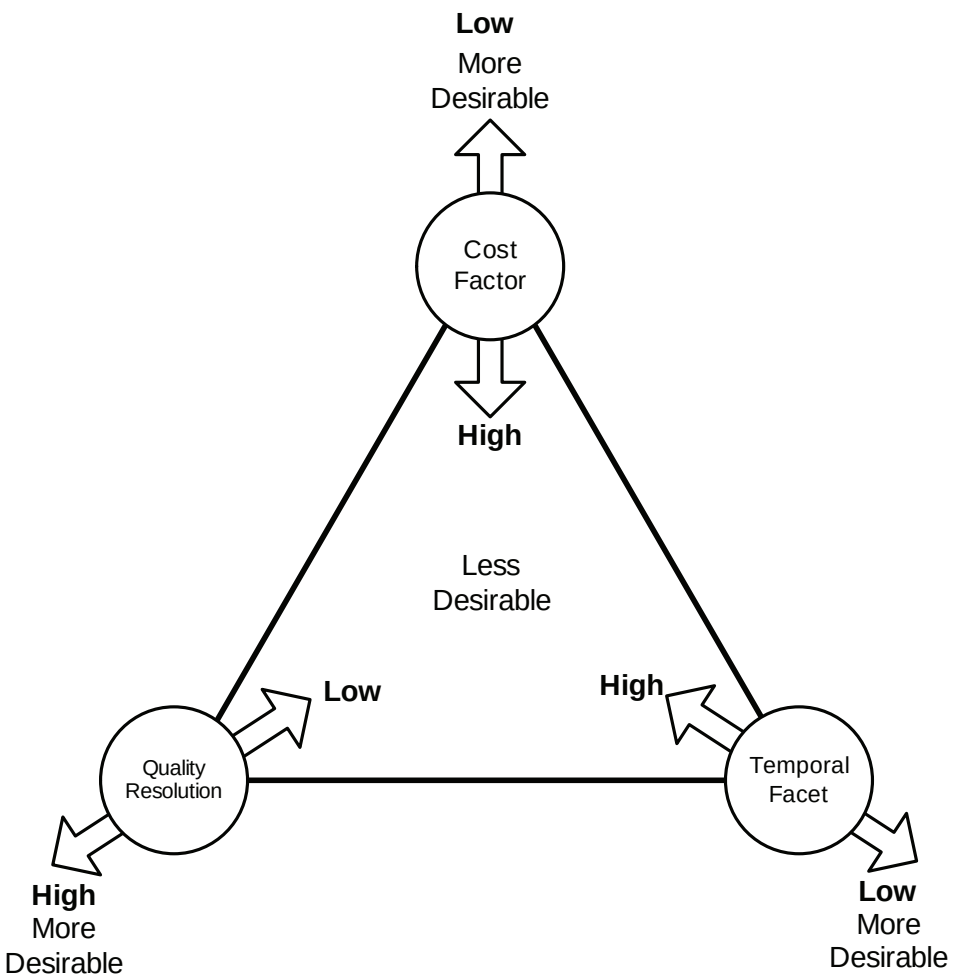
consumers pay high cost as they need higher quality, while other consumers can pay lower cost, as they have lower QoS requirements.

In the following sections, we first explain the concepts involved in the quality, cost, temporal triangle (QCTT), and then present an implementation of the same (Georgievski & Sharda, 2005a).

The three performance aspects—quality, cost, and time—are bound by a tri-partite dependency and thus can be modelled as a triangular relationship, as shown in Figure 3. The QCTT model embodies an inherent restriction on the delivery of QoS, that is, it is possible to achieve the more desirable parameter values only for two of the three performance aspects, while the third aspect must be forced to the less desirable value (Georgievski & Sharda, 2005b).

For example, if a user chooses to have high quality resolution (e.g., large image size, high frame rate), and, the more desirable, low temporal facet (e.g., low delay and jitter), then the cost factor has got to be high. By embedding the quality, cost temporal (QCTT) model in a user interface, we can provide the ability to dynamically man-

Figure 3. Quality, cost, temporal triangle (QCTT) model (Georgievski & Sharda, 2005a)



age QoS even while a multimedia session is in progress.

A multimedia communication session first needs to enter static QoS specifications, and then carry out dynamic QoS management as the session proceeds. An interface based on the QCTT model provides the ability to dynamically manage QoS. Such interfaces are described in the following sections.

Static QoS Specification

Figure 4 shows the user interface developed for negotiating static QoS prior to initiating a multimedia communication session. Using this interface, the user is able to specify the desired QoS, and then interactively negotiate with the system. It uses intuitive GUI elements such as a four colour system, a user status response, and a system status signalling system. These GUI elements allow the user to request the desired QoS, and get feedback if the network can deliver the same (Georgievski & Sharda, 2005a).

Dynamic QoS Management with QCTT

A dynamic QoS management interface is shown in Figure 5. This interface uses the QCTT model for re-negotiating QoS while a communication session is taking place. This is achieved by using three GUI elements: three sliders, buttons, and pivot point displacement. The system feedback GUI elements include: system QoS provision ring and values, and QCT threshold line (Georgievski & Sharda, 2005a).

To specify the desired QoS, the user moves the pivot point in the QCT triangle to a location which indicates the desired values for quality, cost, and temporal parameters.

The system provides visual feedback as follows:

1. **QoS Provision Ring** displays the current QoS parameter values that the system is able to provide.
2. **QoS Provision** values display the current numerical values set for QoS parameters.
3. **QCT Threshold Line** uses a three-colour scheme to provide feedback for displaying desirable and non-desirable values for each aspect.

This system has been tested and a usability analysis has been carried out on the same. While some improvements have been stipulated in the current implementation, overall, it received good assessment from the users (Georgievski & Sharda, 2005a).

Quality of Service on the Move

The ability to provide the requested QoS while roaming will be an important aspect in differentiating various mobile operators. This will determine their ability to hold on to their customers and therefore their revenue stream.

Providing QoS to a customer on the move is highly complex. Factors such as continuous handover, variable quality, dropout, and environmental factors make delivery of consistent QoS highly problematic. QoS provisioning has three main aspects: (1) resource reservation, (2) QoS routing protocol, and (3) Call admission control policy.

The integrated services (IntServ) framework developed under the RFC 1633 aims to provide customised QoS to individual applications (Aggélou, 2003). This is based on two aspects:

1. **Resource Reservation:** Each router needs to know the amount of buffer space and link bandwidth it needs to reserve for a session.
2. **Call Admission:** Each router determines the resources already committed to current sessions it is serving, before accepting the request from a new session.

Figure 4. Static QoS negotiation user interface (Georgievski & Sharda, 2005a)

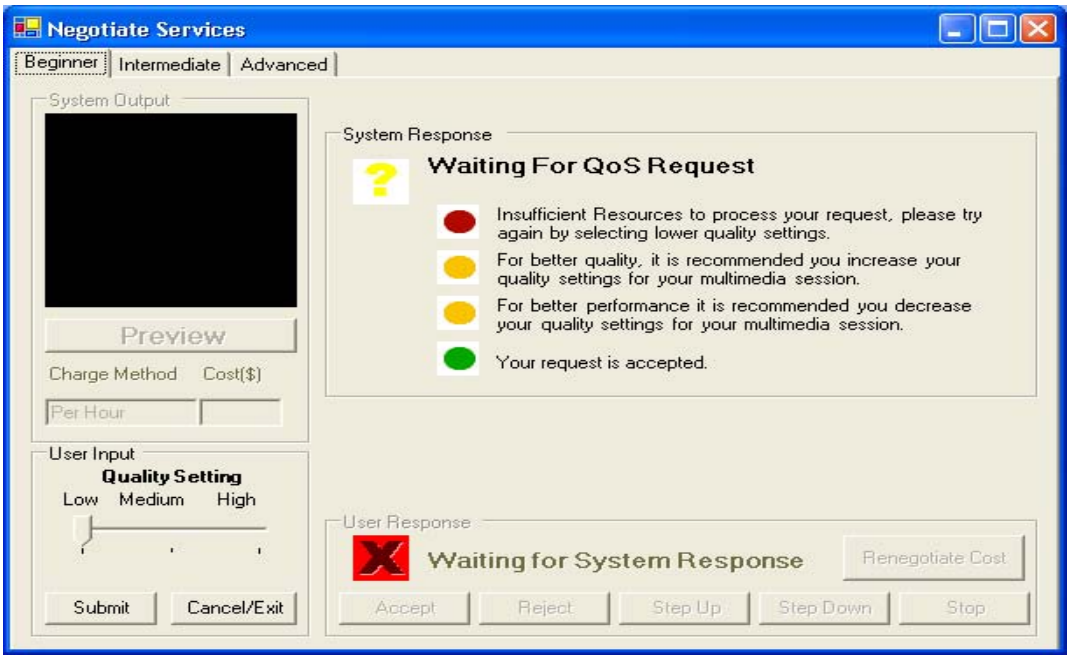


Figure 5. Dynamic QoS management user interface (Georgievski & Sharda, 2005a)

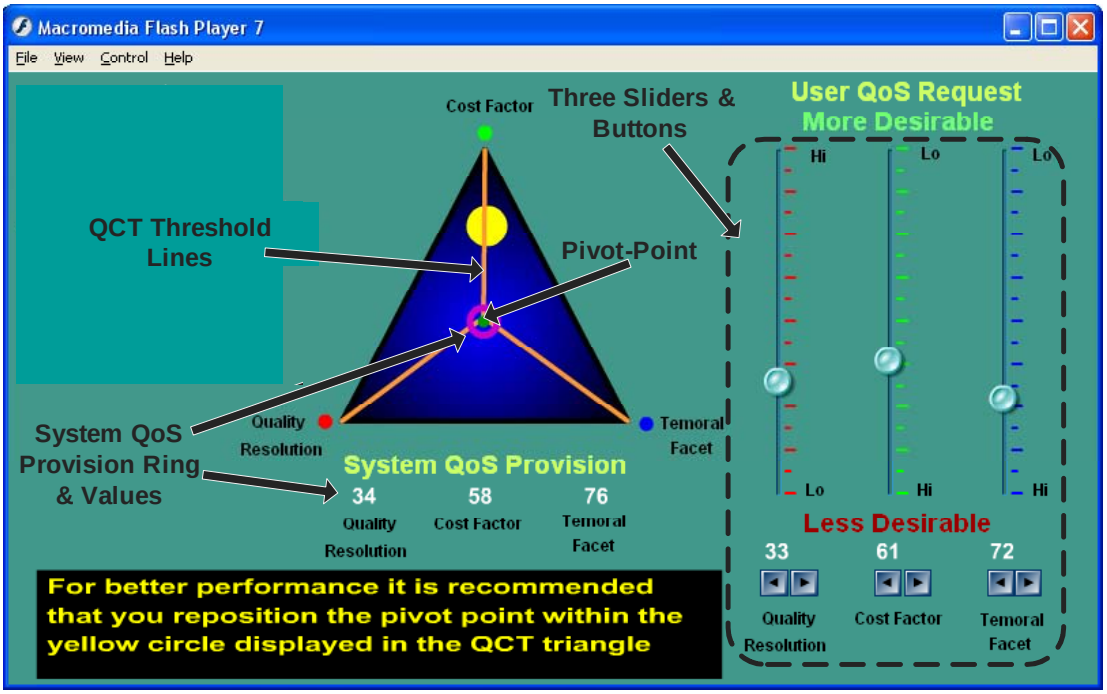

QoS routing is the most important protocol for mobile networks, the main objective specified for this protocol in the RFC 2386 are:

1. **Dynamic Determination of Feasible Paths:** This is based on policy and cost constraints.
2. **Optimisation of Resource Usage:** This requires state-dependent routing schemes.
3. **Graceful Performance Degradation:** This aspect compensates for transient inadequacies using the state-dependent routing scheme.

In summary, a mobile network needs the ability to reserve resources, ensure that a new call is admitted only if enough resources are available, choose the most suitable path to optimise the utilisation of resources, and provide graceful degradation in performance as resources become overloaded.

Quality of Services in Mobile Ad-Hoc Networks

Mobile ad-hoc networks are becoming an important area of investigation. As routing paths are not fixed in an ad-hoc network, QoS routing becomes an even more dynamic problem (Aggélou, 2004). In any ad-hoc network, a variety of routes with differing node capacity and power may be available to transmit data to the destination.

In general, not all routes are capable of providing the required QoS to satisfy the needs of the mobile users. Even when a route is selected that initially meets the user requirements, its error characteristics will not remain constant with time, due to the dynamic nature of routing and node placement in mobile ad-hoc networks. Therefore, ongoing re-routing will be required in an ad-hoc mobile network.

MOSQUITO: Mobile Quality of Service Provision in the Multi-Service Network

The MOSQUITO project, at the University College London, explored a microeconomic approach to resource allocation for providing QoS over multi-service network.

In this protocol, a base station sells bandwidth and QoS guarantees in small auctions to mobile terminals. A simple price setting / bidding function is used to determine the outcome of the auction. This research project aims to explore if:

- Microeconomics can be used for resource allocation.
- The performance of such a system can be measured.
- The algorithm creates a stable system or a chaotic one.
- Chaos can be characterised and controlled.

To use microeconomics for QoS provisioning, such questions need to be answered. Additionally, pricing functions need to be established using some simplifying assumptions; because, without simplifying heuristics, the juxtaposition of a myriad of factors such as pricing, routing, and quality selection will make real-time negotiations impossible.

FUTURE DIRECTIONS

There is no doubt that the future is heading towards mobile communications. And multimedia information will increasingly become the main traffic being transmitted, or blocked, on these networks. One solution to this problem is the so called “brute force” method: that is, “throwing” more bandwidth at the multimedia applications. However, experience shows that as more resources are made available without a viable economic model, the system ultimately gets overloaded.

Therefore, developing QoS systems that provide the user with the ability to negotiate with the network infrastructure are going to be of paramount importance.

Some of the developments in this area point to the following:

1. In the near future, mobile computing and communication systems will suffer from low bandwidth and low performance due to battery limitations.
2. Increasingly, mobile systems will provide higher bandwidth and combine different wireless technologies, such as high performance local wireless networks and wide area networks.
3. Third generation mobile systems will combine IP-traffic with traditional voice traffic.

The next generation of mobile networking technology is called 4G, or "3G and beyond" by IEEE (Aggélou & Tafazolli, 2001). In Japan, NTT DoCoMo is conducting tests under the 4G banner for 100 Mbps speeds with moving terminals, and 1 Gbps for stationary terminals. The first commercial release by NTT DoCoMo is expected in 2010. This technology aims to provide on demand high quality video and audio. 4G will use OFDM (orthogonal frequency division multiplexing), and also OFDMA (orthogonal frequency division multiple access) to better allocate network resources, and service multiple users simultaneously. Unlike the 3G networks, which use both circuit switching and packet switching, 4G will use packet switching only. Additionally, many QoS issues will be handled by developing new protocols. Nonetheless, the author contends that providing the ability to negotiate a compromise between cost, quality, and temporal aspects will remain an important issue.

CONCLUSION

Transmission of multimedia information over mobile networks is becoming increasingly important. New applications are in the offing if such multimedia information can be transmitted with the desired QoS. Text and still images do not pose much problem when transmitting these over mobile networks, as delay and delay variance do not adversely effect the operation of applications using text or still images. JPEG 2000 standard provides a marked improvement over the current standards such as JPEG, GIF, and PNG for still image transmission. Audio and video transmission, especially for full-duplex applications requiring real-time operation, poses the most demanding requirements for providing the desired QoS. While 3G networks, and 4G networks of the future, are capable of providing the required infrastructure for delivering multimedia content with the desired QoS, their user interfaces need to provide the ability to strike the desired balance between quality, cost, and temporal aspects.

ACKNOWLEDGMENT

The author would like to thank Dr. Mladen Georgievski for his useful suggestions and other contributions towards the preparation of this chapter.

Chapter 7.5
Perceptual Semantics

Andrea Cavallaro
Queen Mary University of London, UK

Stefan Winkler
National University of Singapore and Genista Corporation, Singapore

ABSTRACT

The design of image and video compression or transmission systems is driven by the need for reducing the bandwidth and storage requirements of the content while maintaining its visual quality. Therefore, the objective is to define codecs that maximize perceived quality as well as automated metrics that reliably measure perceived quality. One of the common shortcomings of traditional video coders and quality metrics is the fact that they treat the entire scene uniformly, assuming that people look at every pixel of the image or video. In reality, we focus only on particular areas of the scene. In this chapter, we prioritize the visual data accordingly in order to improve the compression performance of video coders and the prediction performance of perceptual quality metrics. The proposed encoder and quality metric incorporate visual attention and use a semantic segmentation stage, which takes into account certain aspects of the cognitive behavior of people when watching a video. This semantic model corresponds to a specific human abstraction, which need not necessarily be characterized by perceptual uniformity. In particular, we concentrate on segmenting moving objects and faces, and we evaluate the perceptual impact on video coding and on quality evaluation.

INTRODUCTION

The development of new compression or transmission systems is driven by the need of reducing the bandwidth and storage requirements of images and video while increasing their perceived visual quality. Traditional compression schemes aim at minimizing the coding residual in terms of mean squared error (MSE) or peak signal-to-noise ratio (PSNR). This is optimal from a purely mathematical but not a perceptual point of view. Ultimately, perception is the more appropriate and more relevant benchmark. Therefore, the objective must be to define a codec that maximizes perceived visual quality such that it produces better quality at the same bit rate as a traditional encoder or the same visual quality at a lower bit rate (Cavallaro, 2005b).

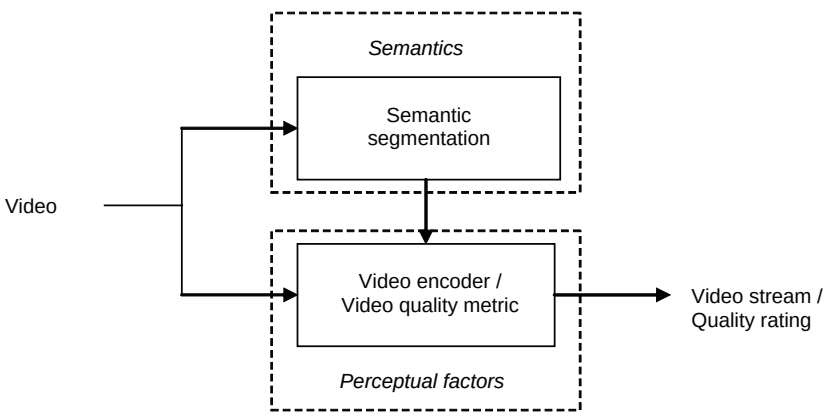
In addition to achieving maximum perceived quality in the encoding process, an important concern for content providers is to guarantee a certain level of quality of service during content distribution and transmission. This requires reliable methods of quality assessment. Although subjective viewing experiments are a widely accepted method for obtaining meaningful quality ratings for a given set of test material, they are necessarily limited in scope and do not lend themselves to monitoring and control applications, where a large amount of content has to be evaluated in real-time or at least very quickly. Automatic quality metrics are desirable tools to facilitate this task. The objective here is to design metrics that predict perceived quality better than PSNR (Winkler, 2005a).

One of the common shortcomings of traditional video coders and quality metrics is the fact that they treat the entire scene uniformly, assuming that people look at every pixel of the image or video. In reality, we focus only on particular areas of the scene, which has important implications on the way the video should be analyzed and processed.

In this chapter, we take the above observations into account and attempt to emulate the human visual system. The idea is to prioritize the visual data in order to improve the compression performance of video coders and the prediction performance of perceptual quality metrics. The proposed encoder and quality metric incorporate visual attention and use a semantic segmentation stage (Figure 1). The semantic segmentation stage takes into account some aspects of the cognitive behavior of people when watching a video. To represent the semantic model of a specific cognitive task, we decompose each frame of the reference sequence into sets of mutually-exclusive and jointly-exhaustive segments. This semantic model corresponds to a specific human abstraction, which need not necessarily be characterized by perceptual uniformity. Since the semantics (i.e., the meaning) are defined through human abstraction, the definition of the semantic partition depends on the task to be performed. In particular, we will concentrate on segmenting moving objects and faces, and we will evaluate the perceptual impact on video coding and on quality evaluation.

The chapter is organized as follows: The section "Cognitive Behavior" discusses the factors influencing the cognitive behavior of people watching a video. The section "Semantic Segmentation" introduces the segmentation stage that generates a semantic partition to be used in video coding and quality evaluation. In "Perceptual Semantics for Video Coding" and "Perceptual Semantics for Video Quality Assessment", we describe how

Figure 1. Flow diagram of the encoder and the quality metric that incorporate factors influencing visual attention and use a semantic segmentation stage



the cognitive behavior can be incorporated into a video coder and a quality metric, respectively. Moreover, the compression performance of the proposed encoder and the prediction performance of the proposed metrics are discussed. In the final section, we draw some conclusions and describe the directions of our current work.

COGNITIVE BEHAVIOR

Visual Attention

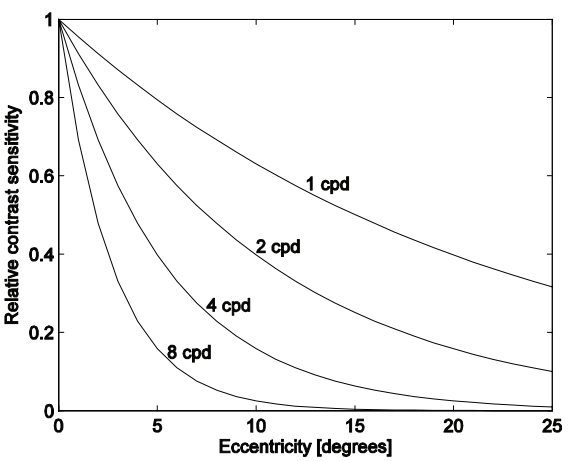
When watching images or video, we focus on particular areas of the scene. We do not scan a scene in raster fashion; instead, our visual attention tends to jump from one point to another. These so-called saccades are driven by a fixation mechanism, which directs our eyes towards objects of interest (Wandell, 1995). Saccades are high-speed eye movements that occur at a rate of 2-3 Hz. We are unaware of these movements because the visual image is suppressed during saccades.

Studies have shown that the direction of gaze is not completely idiosyncratic to individual viewers. Instead, a significant number of viewers will focus on the same regions of a scene (Endo, 1994; Stelmach, 1994). Yarbus (1967) demonstrated in his classic experiments that the saccadic patterns depend on the visual scene as well as the cognitive task to be performed. In other words,"we do not see, we look" (Bajcsy, 1988, p. 1). We focus our visual attention according to task at hand and the scene content.

The reason why this behavior should be taken into account in video encoding and quality assessment is that our visual acuity is not uniform across the entire visual field. In general, visual acuity is highest only in a relatively small cone around the optical axis (the direction of gaze) and decreases with distance from the center. This is partly due to the deterioration of the optical quality of the eye towards the periphery and partly due to the layout of the retina (Banks, Sekuler, & Anderson, 1991). The central region of the retina around the optical axis is called the fovea. It contains the highest density of cones, which are the photoreceptors responsible for vision under usual image or video viewing conditions. Outside of the fovea, the cone density decreases rapidly. This explains why vision is sharp only around the present focus of attention, and the perception of the peripheral field of vision is blurred. In other words, contrast sensitivity is reduced with increasing eccentricity (Robson & Graham, 1981).[1] This effect is also frequency-dependent, as shown in Figure 2.

While the processes governing perception are not completely understood, many different factors contributing to visual attention have been identified (Wolfe, 1998). These include simple stimulus properties such as contrast (regions with high contrast attract attention), size (large objects are more interesting than small ones), orientation, shape (edge-like features or objects with corners are preferred over smooth shapes), hue and intensity (an object with very different color from the background or specific bright colors stands out), or

Figure 2. Loss of spatial contrast sensitivity as a function of eccentricity and stimulus frequency (measured in cycles per degree [cpd]), based on a model by Geisler and Perry (1998)



flicker and motion (see below). In general, an object or feature that stands out from its surroundings in terms of any of the earlier-mentioned factors is more likely to attract our attention. Additionally, the location (most viewers focus on the center of a scene), foreground/background relationship, and context (the task, personal interest, or motivation) influence visual attention. Finally, moving objects and people, in particular their faces (eyes, mouth) and hands, draw our attention.

Computational Models of Attention

While most vision models and quality metrics are limited to lower-level aspects of vision, the cognitive behavior of people when watching video cannot be ignored. Cognitive behavior may differ greatly between individuals and situations, which makes it very difficult to generalize. Furthermore, little is known about the relative importance given to the factors listed above by the human visual system. Nonetheless, based on the above studies and factors contributing to visual attention, a variety of computational models of attention have been developed (Itti & Koch, 2001; Wolfe, 1998). Maeder, Diederich, and Niebur (1996) proposed constructing an importance map for a sequence as a prediction for the focus of attention, taking into account perceptual factors such as edge strength, texture energy, contrast, color variation, and homogeneity. Osberger and Rohaly (2001) developed a segmentation-based model with motion estimation and skin detection, taking into account color, contrast, size, shape, location, and foreground. It was calibrated and tested with eye movement data gathered from an experiment using a large database of still and video scenes. Recently, Navalpakkam and Itti (2005) demonstrated a model that uses task-specific keywords to find relevant objects in a scene and extracts their low-level features to build a visual map of task-relevance.

In this chapter, we focus on two important high-level aspects, namely faces and moving objects.

Attraction of Faces and Moving Objects

People and especially faces are among the objects attracting the most attention.. If there are faces of people in a scene, we will look at them immediately. Furthermore, because of our familiarity with people's faces, we are very sensitive to distortions or artifacts occurring in them. The importance of faces is underlined by a study of image appeal in consumer photography (Savakis, 2000). People in the picture and their facial expressions are among the most important criteria for image selection.

In a similar manner, viewers may also track specific moving objects in a scene. In fact, motion (in particular, in the periphery) tends to attract the viewers' attention. The spatial acuity of the human visual system depends on the velocity of the image on the retina: As the retinal image velocity increases, spatial acuity decreases. The visual system addresses this problem by tracking moving objects with smooth-pursuit eye movements, which minimizes retinal image velocity and keeps the object of interest on the fovea. Smooth pursuit works well even for high velocities, but it is impeded by large accelerations and unpredictable motion (Eckert, 1993). On the other hand, tracking a particular movement will reduce the spatial acuity for the background and objects moving in different directions or at different velocities. An appropriate adjustment of the spatio-temporal contrast sensitivity function (CSF) as outlined by Daly (1998) to account for some of these sensitivity changes can be considered as a first step in modeling such phenomena.

Based on the observations of this section, the proposed video coder and perceptual quality metric take into account both low-level and high-level aspects of vision. To achieve this, a segmentation stage is added to the video coder and to the quality metric to find regions of interest. The segmentation output then guides a pre-processing step in coding and a pooling process in video quality evaluation by giving more weight to the regions with semantically higher importance.

Figure 3. (a) Example of face detection result on the test sequence Susie and (b) corresponding segmentation mask (white: foreground, black: background)

(a) (b)

SEMANTIC SEGMENTATION

The high-level contribution to the cognitive behavior of people when watching a video is taken into account by means of semantic segmentation. To represent the semantic model of a specific cognitive task, we decompose each frame of the sequence into sets of mutually-exclusive and jointly-exhaustive segments. In general, the topology of this semantic partition cannot be expressed using homogeneity criteria, because the elements of such a partition do not necessarily possess invariant properties. As a consequence, some knowledge of the objects we want to segment is required. We will consider two cases of such *a priori* information, namely segmentation of faces and segmentation of moving objects. The final partition will be composed of foreground areas and background areas of each image.

Color segmentation and feature classification can be exploited to segment faces of people. A number of relatively robust algorithms for face segmentation are based on the fact that human skin colors are confined to a narrow region in the chrominance (C_b, C_r) plane (Gu, 1999), when the global illumination of the scene does not change significantly. Otherwise, methods based on tracking the evolution of the skin-color distribution at each frame based on translation, scaling, and rotation of skin color patches in the color space can be used (Sigal, 2004). One of the limits of approaches based on color segmentation is that the resulting partition may include faces as well as body parts. To overcome this problem, a combination of color segmentation with facial feature extraction (Hsu, 2002) can be used. Other approaches use feature classifiers only. Viola and Jones (2004) proposed a face detector based on a cascade of simple classifiers and on the integral image. This detector is a multi-stage classification that works as follows. First, features similar to Haar basis functions are extracted from the gray-level integral image. Next, a learning step called AdaBoost is used to select a small number of relevant features. This pruning process selects weak classifiers that depend on one feature only. Finally, the resulting classifiers are combined in a cascade structure. With such an approach, a face cannot be reliably detected when it appears small or not frontal. However, in such a situation the face in general does not attract viewers' attention as much as a frontal or large face. Therefore, this limitation will not affect the proposed approach in a significant way. Figure 3 shows an example of face detection for the test sequence Susie.

To segment moving objects, motion information is used as semantics. The motion of an object is usually different from the motion of background and other surrounding objects. For this reason, many extraction methods make use of motion information in video sequences to segment objects (Cavallaro, 2004a). Change detection is a typical

tool used to tackle the problem of object segmentation based on motion. Different change detection techniques can be employed for moving camera and static camera conditions. If the camera moves, change detection aims at recognizing coherent and incoherent moving areas. The former correspond to background areas, the latter to video objects. If the camera is static, the goal of change detection is to recognize moving objects (foreground) and the static background. The semantic segmentation discussed here addresses the static camera problem and is applicable in the case of a moving camera after global motion compensation.

The change detector decides whether in each pixel position the foreground signal corresponding to an object is present. This decision is taken by thresholding the frame difference between the current frame and a frame representing the background. The frame representing the background is dynamically generated based on temporal information (Cavallaro, 2001). The thresholding aims at discarding the effect of the camera noise after frame differencing. A locally adaptive threshold, $\tau(i,j)$, is used that models the noise statistics and applies a significance test. To this end, we want to determine the probability that frame difference at a given position *(i,j)* is due to noise, and not to other causes. Let us suppose that there is no moving object in the frame difference. We refer to this hypothesis as the null hypothesis, H_0. Let *g(i,j)* be the sum of the absolute values of the frame difference in an observation window of *q* pixels around *(i,j)*. Moreover, let us assume that the camera noise is additive and follows a Gaussian distribution with variance σ. Given H_0, the conditional probability density function (pdf) of the frame difference follows a χ^2_q distribution with *q* degrees of freedom defined by:

$$f(g(i,j) \mid H_o) = \frac{1}{2^{q/2}\sigma^q \Gamma(q/2)} g(i,j)^{(q-2)/2} e^{-g(i,j)^2/2\sigma^2}$$

$\Gamma(\cdot)$ is the Gamma function, which is defined as $\Gamma(x+1) = x\Gamma(x)$, and $\Gamma(1/2) = \sqrt{\pi}$. To obtain a good trade-off between robustness to noise and accuracy in the detection, we choose *q=25* (5-by-5 window centered in *(i,j)*). It is now possible to derive the significance test as:

$$P\{g(i,j) \geq \tau(i,j) \mid H_0\} = \frac{\Gamma(q/2, g(i,j)^2/2\sigma^2)}{\Gamma(q/2)} .$$

When this probability is smaller than a certain significance level, α, we consider that H_0 is not satisfied at the pixel position *(i,j)*. Therefore we label that pixel as belonging to a moving object. The significance level α is a stable parameter that does not need manual tuning over a sequence or for different sequences. Experimental results indicate that valid values fall in the range from 10^{-2} to 10^{-6}.

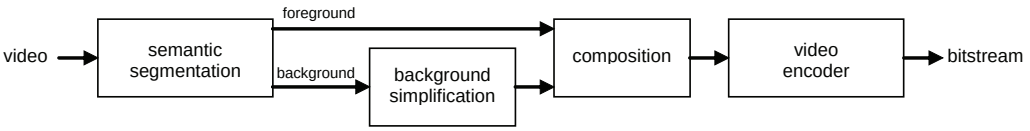
(b)

Figure 5. Using semantic segmentation for perceptual video coding



An example of a moving object segmentation result is shown in Figure 4.

The video partitions generated with semantic segmentation are then used in the video encoding process and in the quality evaluation metric as described in the following sections.

PERCEPTUAL SEMANTICS FOR VIDEO CODING

A video encoder that exploits semantic segmentation facilitates the improvement of video compression efficiency in terms of bandwidth requirements as well as visual quality at low bit rates. Using semantic decomposition, the encoder may adapt its behavior to code relevant and non-relevant portions of a frame differently. This adaptation can be achieved with a traditional frame-based encoder by semantically pre-filtering the video prior to coding (Figure 5).

Video Coders

The semantic pre-filtering is obtained by exploiting semantics in a traditional frame-based encoding framework, such as MPEG-1. The use of the decomposition of the scene into meaningful objects prior to encoding, referred here as semantic pre-filtering, helps support low-bandwidth transmission. The areas belonging to the foreground class are used as the region of interest. The areas not included in the region of interest are lowered in importance by using a low-pass filter. The latter solution simplifies the information in the background, while still retaining essential contextual information. The simplification of the background allows for a reduction of information to be coded. The use of a simplified background so as to enhance the relevant objects aims at taking advantage of the task-oriented behavior of the human visual system for improving compression ratios. The work reported by Bradley (2003) demonstrates that an overall increase in image quality can be obtained when the increase

Figure 6. Simplification of contextual information: (a) Sample frame from the test sequence Hall Monitor; (b) simplification of the whole frame using a low-pass filter; (c) selective low-pass filtering based on semantic segmentation results allows one to simplify the information in the background while still retaining essential contextual information

(a) (b) (c)

in quality of the relevant areas of an image more than compensates for the decrease in quality of the image background. An example of this solution, which aims at mimicking the blur occurring in the retina due to foveation (Itti, 2004) using high-level semantic cues, is reported in Figure 6.

Another way to take into account less relevant portions of an image before coding is to take advantage of the specifics of the coding algorithm. In the case of block-based coding, each background macro-block can be replaced by its DC value only. While this approach also has the effect of frequency reduction and loss of detail, it may lead to unacceptably strong blocking artifacts in the video.

An alternative approach is using object-based encoding. In such a case, the encoder needs to support the coding of individual video objects, such as for MPEG-4, object-based mode (Sikora, 1997). With this solution, each video object is assigned to a distinct object class, according to its importance in the scene. The encoding quality can be set depending on the object class: the higher the relevance, the higher the encoding quality. One advantage of this approach is the possibility of controlling the sequencing of objects. Video objects may be encoded with different degrees of compression, thus allowing better granularity for the areas in the video that are of more interest to the viewer. Moreover, objects may be decoded in their order of priority, and the relevant content can be viewed without having to reconstruct the entire image. Finally, sprite coding could be used when an image representing the background is sent to the receiver once and then objects are encoded and composed with an appropriate portion of the background at the receiver side. However, these solutions require that objects are tracked after

Figure 7. Comparison between standard MPEG–1 encoding and perceptually pre-filtered MPEG–1 encoding at 150 kbit/s. (c) (d)

segmentation (Cavallaro, 2005a), thus increasing the complexity of the approach.

Results

The results presented in this section illustrate the impact of semantic pre-filtering on the encoding performance of a frame-based coder. Sample results are shown from the MPEG-4 test sequence Hall Monitor and from the MPEG-7 test sequence Highway. Both sequences are in CIF format at 25 Hz. The background is simplified using a Gaussian 9x9 low-pass filter with μ=0 and σ=2, where μ and σ are the mean and standard deviation of the filter, respectively. The TMPGEnc 2.521.58.169 encoder using constant bit-rate (CBR) rate control was used for the encoding.

Figure 7 shows a sample frame from each test sequence coded with MPEG-1 at 150 kbit/s with and without semantic pre-filtering. Figure 8 shows magnified excerpts of both test sequences coded with MPEG–1 at 150 kbit/s. Figure 8(a, b) shows a blue truck entering the scene at the beginning of the Highway sequence. Coding artifacts are less disturbing on the object in Figure 8(b) than in Figure 8(a). Moreover, the front-left wheel of the truck is only visible with semantic pre-filtering, Figure 8(b). Similar observations can be made for Figure 8(c, d), which shows the person that carries a monitor in the Hall Monitor sequence. The amount of coding artifacts is notably reduced by semantic pre-filtering as shown in Figure 8(d). In particular, the person's facial features and clothes are clearly visible in Figure 8(d), whereas they are corrupted by coding artifacts in Figure 8(c).

PERCEPTUAL SEMANTICS FOR VIDEO QUALITY ASSESSMENT

A quality measure based on semantic segmentation is useful for end-to-end communication architectures aiming at including perceptual requirements for an improved delivery of multimedia information. Predicting subjective ratings using an automatic visual quality metric with higher accuracy than peak signal-to-noise ratio (PSNR) has been the topic of much research in recent years. However, none of today's metrics quite achieves the reliability of subjective experiments.

Two approaches for perceptual quality metric design can be distinguished (Winkler, 2005b): One

Figure 8. Details of sequences encoded at 150 kbit/s: (a) Frame 44 of Highway MPEG–1 encoded; (b) Frame 44 of Highway MPEG–1 encoded after perceptual pre-filtering (c) Frame 280 of Hall Monitor MPEG–1 encoded; (d) Frame 280 of Hall Monitor MPEG–1 encoded after perceptual pre-filtering; notice that the front left wheel of the truck is visible with semantic pre-filtering only (b). (a) (b) (c) (d)

class of metrics implements a general model of low-level visual processing in the retina and the early visual cortex. Metrics in this class typically require access to the reference video for difference analysis. The other class of metrics looks for specific features in the image, for example, compression artifacts arising from a certain type of codec, and estimates their annoyance.

To demonstrate the use of perceptual semantics with both classes of metrics, we describe a specific implementation from each class here. The first is a full-reference perceptual distortion metric (PDM) based on a vision model, and the second is a no-reference video quality metric based on the analysis of common artifacts. These are then combined with perceptual semantics to achieve a better prediction performance (Cavallaro & Winkler, 2004).

Full-Reference Quality Metric

The full-reference PDM is based on a contrast gain control model of the human visual system that incorporates spatial and temporal aspects of vision as well as color perception (Winkler, 1999). A block diagram of this metric is shown in Figure 9. The metric requires both the test sequence and the corresponding reference sequence as inputs.

The input videos are first converted from YUV or RGB to an opponent-color space, which is closer to the perceptual representation of color information. Each of the resulting three components is then subjected to a spatio-temporal decomposition, which is implemented as a filter bank. This emulates the different mechanisms in the visual system, which separate the input signals according to their color, frequency, orientation, and other characteristics. The sensitivity to the information in every channel is different, so the channels are weighted according to contrast sensitivity data.

The subsequent contrast gain control stage models pattern masking, which is one of the most critical components of video quality assessment, because the visibility of distortions is highly dependent on the local background. Masking is strongest between stimuli located in the same perceptual channel, and becomes weaker for stimuli with differing characteristics. The perceptual decomposition allows us to take many of these intra- and inter-channel masking effects into account. Within the process of contrast gain control, masking occurs through the inhibitory effect of the various perceptual channels.

At the output of the contrast gain control stage, the differences between the reference and the test video are computed for each channel and then combined ("pooled") into a distortion measure or quality rating according to the rules of probability summation.

No-Reference Quality Metric

The no-reference quality metric estimates visual quality based on the analysis of common coding and transmission artifacts found in the video (Win-

Figure 9. Block diagram of the perceptual distortion metric (PDM)

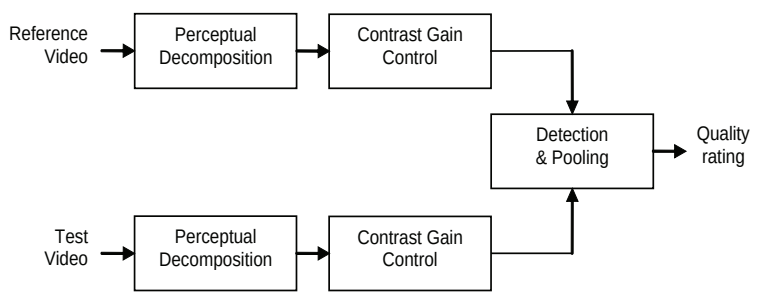

Figure 10. Block diagram of no-reference quality metric

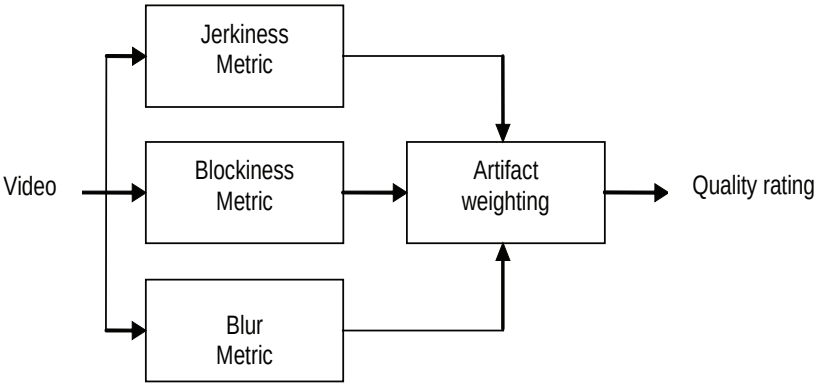

kler & Campos, 2003). These artifacts include blockiness, blur, and jerkiness. A block diagram of this metric is shown in Figure 10. It does not need any information about the reference sequence.[2] The use of a no-reference metric is particularly interesting here because semantic segmentation does not require a reference video either.

The blockiness metric looks for typical block patterns in a frame. These block patterns are an artifact common to DCT block-based image and video compression methods such as JPEG or MPEG. Blocks often form regular horizontal or vertical structures in an image, which appear as characteristic peaks in the spectrum of spatial difference signals. If the blocks are not regular, each block has to be identified individually based on its texture and boundaries. The spectral power peaks and the boundary contrasts are used to compute a measure of overall blockiness.

Blur is a perceptual measure of the loss of fine detail in the image. It is due to the attenuation of high frequencies at some stage of the recording or encoding process. The blur metric is based on the assumption that edges, which often represent object contours, are generally sharp. Compression has a smearing effect on these edges. The blur metric thus looks for significant edges in an image and measures their width. This local edge smear is then averaged over the entire image for a global estimate of blur.

The jerkiness metric is a temporal metric dedicated to measuring the motion rendition in the video. Jerkiness is a perceptual measure of frozen pictures or motion that does not look smooth. The primary causes of jerkiness are network congestion and/or packet loss. It can also be introduced by the encoder dropping or repeating frames in an effort to achieve the given bit-rate constraints. The jerkiness metric takes into account the video frame rate as well as the amount of motion activity in the video.

Both of these metrics can make local quality measurements in small sub-regions over a few frames in every video. The process of combining these low-level contributions into an overall quality rating is guided by the result of the semantic segmentation stage as shown in Figure 11. The metrics described here attempt to emulate the human visual system to prioritize the visual data in order to improve the prediction performance of a perceptual distortion metric. The resulting semantic video quality metric thus incorporates both low-level and high-level aspects of vision. Low-level aspects are inherent to the metric and include color perception, contrast sensitivity, masking and artifact visibility. High-level aspects take into account the cognitive behavior of an observer when watching a video through semantic segmentation.

Figure 11. Quality assessment using perceptual semantics

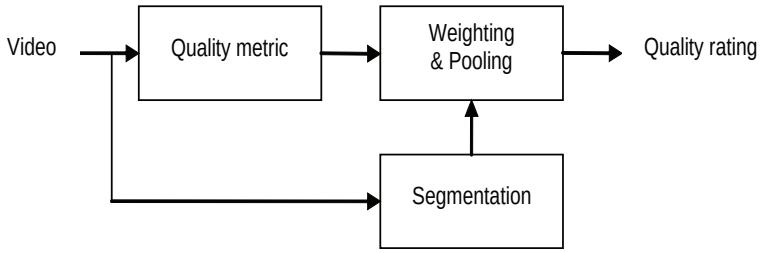

Figure 12. Sample frames from selected test sequences

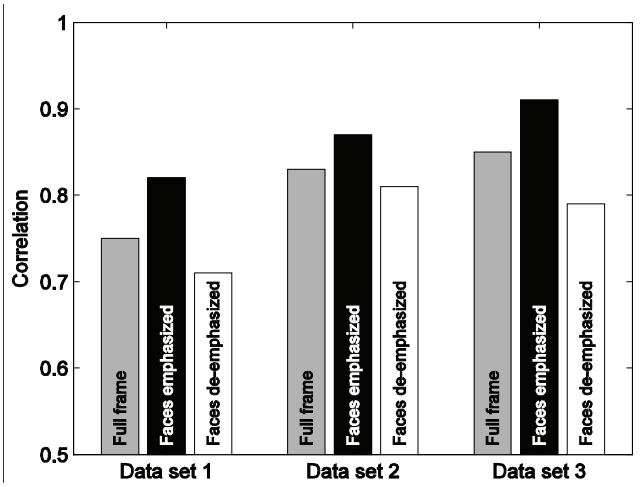
Figure 13. Prediction performance with and without segmentation; correlations are shown for the metrics applied uniformly across the full frame (gray bars), with an emphasis on the areas resulting from face segmentation (black bars), and the complementary emphasis (white bars)



Evaluation and Results

To evaluate the improvement of the prediction performance due to face segmentation, we compare the ratings of the regular full-frame metrics with those of the segmentation-supported metrics for different data sets. We focus our evaluation on the special case when faces attract the attention of an observer. We quantify the influence of variations of quality of the relevant parts of the content on perceived video quality.

We used test material and subjective ratings from three different subjective testing databases:

1. VQEG Phase I database (VQEG, 2000): This database comprises mainly TV material with 16 test conditions. Three relevant scenes were selected from this database to evaluate the full-reference PDM.
2. PC video database (Winkler, 2001): This database was created with CIF-size video and various DirectShow codecs at bit-rates of 1-2 Mb/s, for a total of eight test conditions. We picked two scenes from this database to evaluate the full-reference PDM.
3. Internet streaming database (Winkler & Campos, 2003): This database contains clips encoded with MPEG-4, Real Media and Windows Media at 256 and 512 kb/s, as well as some packet loss (seven conditions in total). Four scenes from this database were used. Due to the test conditions here, these sequences cannot be properly aligned with the reference. Therefore, we use this set for the evaluation of our no-reference metric.

The scenes we selected from these databases contain faces at various scales and with various amounts of head and camera movements. Some examples are shown in Figure 12.

The results of the evaluation for our three data sets are shown in Figure 13. Segmentation generally leads to a better agreement between the metric's predictions and the subjective ratings. The trend is the same for all three data sets, which indicates that face segmentation is useful for augmenting the predictions of quality metrics. Moreover, giving lower weights to faces leads to a reduced prediction performance. This observation also supports the conclusion that semantic segmentation helps predicting perceived quality. As expected, the improvement is most noticeable for the scenes where faces cover a substantial part of the frame. Segmentation is least beneficial for sequences in which the faces are quite small and the distortions in the background introduced by some test conditions are more annoying to viewers than in other regions (as is the case with data set 2).

SUMMARY

We analyzed factors influencing visual attention and how they can be incorporated in a video encoder and in a perceptual distortion metric using segmentation. We looked at the special cases of moving object and face segmentation, and we evaluated the performance improvement of a frame-based encoder and video quality metrics combined with a segmentation stage.

In video coding, the advantages of segmentation support have been demonstrated at low-bit rates with test sequences containing moving objects. In quality evaluation, the advantages of segmentation support have been demonstrated with test sequences showing human faces, resulting in better agreement of the predictions of a perceptual quality metric with subjective ratings. Even if the segmentation support is adding complexity to the overall system, the algorithms used for the detection of faces and moving objects are running in real-time on standard personal computers. Moreover, the proposed perceptual video coding method does not add any overhead to the bitstream, thus allowing interoperability with existing decoders.

Current work includes the extension of the technique and results to the evaluation of multimedia information, including graphics, audio, and video for applications such as augmented reality and immersive spaces.

Chapter 7.6
A Multidimensional Approach for Describing Video Semantics

Uma Srinivasan
CSIRO ICT Centre, Australia

Surya Nepal
CSIRO ICT Centre, Australia

ABSTRACT

In order to manage large collections of video content, we need appropriate video content models that can facilitate interaction with the content. The important issue for video applications is to accommodate different ways in which a video sequence can function semantically. This requires that the content be described at several levels of abstraction. In this chapter we propose a video metamodel called VIMET and describe an approach to modeling video content such that video content descriptions can be developed incrementally, depending on the application and video genre. We further define a data model to represent video objects and their relationships at several levels of abstraction. With the help of an example, we then illustrate the process of developing a specific application model that develops incremental descriptions of video semantics using our proposed video metamodel (VIMET).

INTRODUCTION

With the convergence of Internet and Multimedia technologies, video content holders have new opportunities to provide novel media products and services, by repurposing the content and delivering it over the Internet. In order to support such applications, we need video content models that allow video sequences to be represented and managed at several levels of semantic abstraction. Modeling video content to support semantic retrieval is a hard task, because *video semantics* means different things to different people. The MPEG-7 Community (ISO/ISE 2001) has spent considerable effort and time in coming to grips with ways to describe video semantics at several levels, in order to support a variety of video applications. The task of developing content models that show the relationships across several levels of video content descriptions has been left to application developers. Our aim in this chapter is to

provide a framework that can be used to develop video semantics for specific applications, without limiting the modeling to any one domain, genre or application.

The Webster Dictionary defines the meaning of semantics as "the study of relationships between "signs and symbols" and what they represent." In a way, from the perspective of feature analysis work (MPEG, 2000; Rui, 1999; Gu, 1998; Flickner et al., 1995; Chang et al. 1997; Smith & Chang, 1997), low- level audiovisual features can be considered as a subset, or a part of, visual "signs and symbols" that convey a meaning. In this context, audio and video analysis techniques have provided a way to model video content using some form of constrained semantics, so that video content can be retrieved at some basic level such as shots. In the larger context of video information systems, it is now clear that feature analyses alone are not adequate to support video applications. Consequently, research focus has shifted to analysing videos to identify higher-level semantic content such as objects and events. More recently, video semantic modeling has been influenced by film theory or semiotics (Hampapur, 1999; Colombo et al., 2001; Bryan-Kinns, 2000), where a meaning is conveyed through a relationship of signs and symbols that are manipulated using editing, lighting, camera movements and other cinematic techniques. Whichever theory or technology one chooses to follow, it is clear that we need a video model that allows us to specify relationships between signs and symbols across video sequences at several levels of interpretation (Srinivasan et al., 2001).

The focus of this chapter is to present an approach to modeling video content, such that video semantics can be described incrementally, based on the application and the video genre. For example, while describing a basketball game, we may wish to describe the game at several levels: the colour and texture of players' uniforms, the segments that had the crowd cheering loudly, the goals scored by a player or a team, a specific movement of a player and so on. In order to facilitate such descriptions, we have developed a framework that is generic and not definitive, but still supports the development of application specific semantics.

The next section provides a background survey of some of these approaches used to model and represent the semantics associated with video content. In the third section, we present our Video Metamodel Framework (VIMET) that helps to model video semantics at different levels of abstraction. It allows users to develop and specify their own semantics, while simultaneously exploiting results of video analysis techniques. In the fourth section, we present a data model that implements the VIMET metamodel. In the fifth section we present an example. Finally, the last section provides some conclusions and future directions.

BACKGROUND

In order to highlight the challenges and issues involved in modeling video semantics, we have organized video semantic modeling approaches into four broad categories and cite a few related works under each category.

Feature Extraction Combined with Clustering or Temporal Grouping

Most approaches that fall under this category have focused on extracting visual features such as colour and motion (Rui et al., 1999; Gu, 1998; Flickner et al., 1995), and abstracting visual signs to identify semantic information such as objects, roles, events and actions. Some approaches have also included audio analysis to extract semantics from videos (MPEG MAAATE, 2000). We recognize two types of features that are extracted from videos: static features and motion-based features. Static features are mostly perceptual features extracted from stationary images or

single frames. Examples are colour histograms, texture maps, and shape polygons (Rui et al., 1999). These features have been exploited as attributes that represent colour, texture and shape of objects and images in a single frame. Motion-based features are those that exploit the basic spatiotemporal nature of videos (Chang et al., 1997). Examples of motion-based low-level features are motion-vectors for visual features and frequency bands for audio signals. These features have been used to segment videos into shots or temporal segments. Once the features are extracted, they are clustered into groups or segmented into temporal units to classify video content at a higher semantic level. Hammoud et al. (2001) use such an approach for modeling video semantics. They extract shots, use clustering to identify similar shots, and use a time-space graph to represent temporal relationships between clusters for extracting scenes as semantic units. Hacid et al. (2000) present a database approach for modeling and querying video data. They use two layers for representing video content: feature and content layer, and semantic layer. The lowest layer is characterized by a set of techniques and algorithms for visual features and relationships. The top layer contains objects of interest, their description and their relationships. A significant component of this approach is the use of temporal cohesion to attach semantics to the video.

Relationship-Based Approach for Modeling Video Semantics

This approach is based on understanding the different types of relationships among video objects and their features. For example, in videos, spatial and temporal relationships of features that occur over space and time have contributed significantly for identifying content at a higher level of abstraction. For example, in the MPEG domain, DCT coefficients and motion vectors are compared over a temporal interval to identify shots and camera operations (Meng et al., 1995). Similarly, spatial relationships of objects over multiple frames are used to identify moving objects (Gu, 1998). Smith and Benitez (2000) present a Multimedia-Extended Entity Relationship (MM-EER) model that captures various types of structural relationships such as spatiotemporal, intersection, and composition, and provide a unified multimedia description framework for content-based description of multimedia in large databases. The modeling framework supports different types of relationships such as generalization, aggregation, association, structural relationship, and intensional relationship. Baral et al. (1998) also extended ER diagrams with a special attribute called "core." This attribute stores the real object in contrast to the abstraction which is reflected in the rest of the attributes. Pradhan et al. (2001) propose a set of interval operations that can be used to build an answer interval to the given query by synthesizing video interval containing keywords similar to that of the query.

Theme-Based Annotation Synchronized to Temporal Structure

This approach is based on using textual annotations synchronized to a temporal structure (Yap et al. 1996). This approach is often used in television archives where segments are described thematically and linked to temporal structures such as shots or scenes. Hjelsvold and Midtstraum (1994) present a general data model for sharing and reuse of video materials. Their data model is based on two basic ideas: temporal structural representation of video and thematic annotations and relationships between them. Temporal structure of video includes frame, shot, scene, sequence, and so forth. The data model allows users to describe frame sequences using thematic annotations. It allows detailed descriptions of the content of the video material, which are not necessarily linked to structural components. More often they are linked to arbitrary frame sequences by establishing a relationship between the frame sequences

and relevant annotations, which are independent of any structural components. Other works that fall under this category include (Bryan-Kinns, 2000; Srinivasan, 1999).

Approach Based on Knowledge Models and Film Semiotics

As we move up the semantic hierarchy to represent higher-level semantics in videos, in addition to extracting features and establishing their relationships, we need knowledge models that help us understand higher-level concepts that are specific to a video genre. Models that aim to represent content at higher semantic levels use some form of knowledge models or semiotic and film theory to understand the semantics of videos. Film theory or semiotics describes how a meaning is conveyed through a relationship of signs and symbols that are meaningful to a particular culture. This is achieved by manipulation of editing, lighting, camera movements and other cinematic techniques.

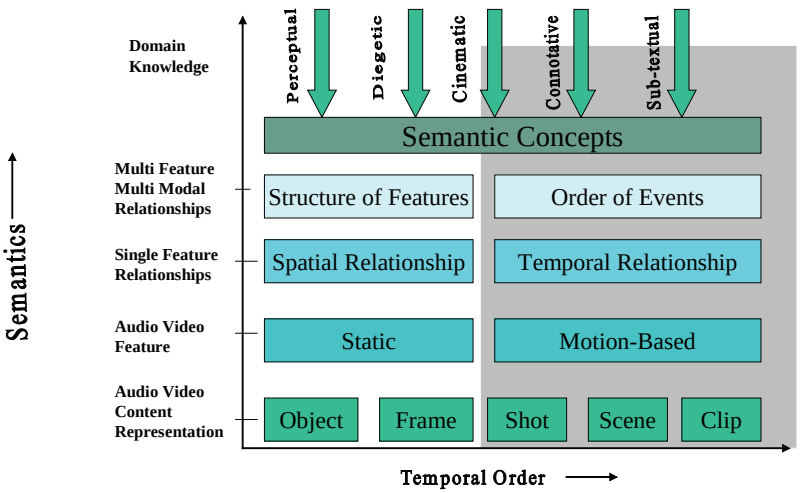
Colombo et al. (2001) present a model that allows retrieval of commercial content based on their salient semantics. The semantics are defined from the semiotic perspective, that is, collections of signs and semantic features like colour, motion, and so forth, are used to build semantics. It classifies commercials into four different categories based on semiotics: practical, critical, utopic and playful. A set of rules is then defined to map the set of perceptual features to each of the four semiotic categories for commercials.

Bryan-Kinns (2000) presents a framework (VCMF) for video content modeling which represents the structural and semantic regularities of classes of video recordings. VCMF can incorporate many domain-specific knowledge models to index video at the semantic level.

Hampapur (1999) presents an approach based on the use of knowledge models to build domain-specific video information systems. His aim is to provide higher-level semantic access to video data. The knowledge model proposed in their paper includes the semantic model, cinematic model and physical world model. Each model has several sub-models; for example, the cinematic model includes a camera motion model and a camera geometry model.

We realize that the above categories are not mutually exclusive and many models and frameworks use a combination of two or more of these modeling strategies.

Figure 1. A multidimensional data model for building semantics (the shadow part represents the temporal (dynamic) component)



We now describe our metamodel framework. It uses feature extraction, multimodal relationships, and semiotic theory to model video semantics at several levels of abstraction. In a way, we use a combination of the four approaches described above.

VIDEO METAMODEL (VIMET)

Figure 1 shows the video metamodel which we call VIMET. The horizontal axis shows the temporal dimension of the video and the vertical axis shows the semantic dimension. A third dimension represents the domain knowledge associated with specialized interpretations of a film or a video (Metz, 1974; Lindley & Srininvasan, 1999). The metamodel represents: (1) static and motion-based features in both audio and visual domain, (2) different types of spatial and temporal relationships, (3) multimodal, multifeature relationships to identify events, and (4) concepts influenced by principles of film theory. The terms and concepts used in the metamodel are described below.

The bottom layer shows the standard way in which a video is represented to show temporal granularity.

- **Object:** It represents a single object within a frame. An object may be identified manually or automatically if an appropriate object detection algorithm exists.
- **Frame:** It represents a single image of a video sequence. There are 25 frames (or 30 in certain video formats) in a video of one-second duration.
- Shot: A shot is a temporal video unit between two distinct camera operations. Shot boundaries occur due to different types of camera operations such as cuts, dissolves, fades and wipes. There are various techniques used to determine shots. For example, DCT coefficients are used in MPEG videos to identify distinct shot boundaries.
- **Scene:** A scene is a series of consecutive shots constituting a unit from the narrative point of view sharing some thematic visual content. For example, a video sequence that shows Martina Hinges playing the "game point" in the 1997 Australian open final is a thematic scene.
- **Clip:** A clip is an arbitrary length of video used for a specific purpose. For example, a video sequence that shows tourist places around Sydney is a video clip made for tourism purpose.

The semantic dimension helps model semantics in an incremental way using features and their relationships. It uses information from the temporal dimension to develop the semantics.

- **Static features:** Represent features extracted from objects and frames. Shape, color and texture are examples of static features extracted from the objects. Similarly, global color histogram and average colors are examples of features extracted from a frame.
- **Motion-based features:** Represent features extracted from video using motion-based information. An example of such a feature is motion vector.

The next level of conceptualisation occurs when we group individual features to identify objects and events using some criteria based on spatial and/or temporal relationships.

- **Spatial Relationships:** Two types of spatial relationships are possible for videos: topological relationships and directional relationships. Topological relationships include relations such as contains, covered by, and disjoint (Egenhofer & Franzosa, 1991). Directional relationships include relations such as right-of, left-of, above and below (Frank, 1996).

- **Temporal Relationships:** This includes the most commonly used temporal relationship from Allen's 13 temporal relationships (Allen, 1983). These include temporal relations such as before, meets, overlaps, finishes, starts, contains, equals, during, started by, finished by, overlapped by, met by and after.

Moving further up in the semantic dimension, we use multiple features both in the audio and the visual domain, and establish (spatial and temporal) relationships across these multimodal features to model higher-level concepts. In the temporal dimension, this helps us identify semantic constructs based on structure of features and order of events occurring in a video.

- **Structure of Features:** Represents patterns of features that define a semantic construct. For example, a group of regions connected through some spatial relationship over multiple frames, combined with some loudness value spread over a temporal segment, could give an indication of a particular "event" occurring in the video.
- **Order of Events:** Represents recurring pattern of events identified manually or detected automatically using multimodal feature relationships. For example, camera pan is a cinematic event that is derived by using a temporal relationship of motion vectors. (The motion vectors between consecutive frames due to the pan should point in a single direction that exhibits a strong modal value corresponding to the camera movement.) Similarly, a sudden burst of sound is a perceptual auditory event. These cinematic and perceptual events may be arranged in certain sequence from a narrative point of view to convey a meaning. For example, a close-up followed by a loud sound could be used to produce a dramatic effect. Similarly, a crowd cheer followed by scorecard could be used to determine field goals in basketball videos. (We will describe this in greater details later in our example.)

Modeling "the meaning" of a video, shot, or sequence requires the description of the video object at several levels of interpretation. Film semiotics, pioneered by the film theorist Christian Metz (1974), has identified five levels of cinematic codification that cover visual features, objects, actions and events depicted in images together with other aspects of the meaning of the images. These levels are represented in the third dimension of the metamodel. The different levels interact together, influencing the domain knowledge associated with a video.

- **Perceptual level:** This is the level at which visual phenomena become perceptually meaningful, the level at which distinctions are perceived by the viewer. This is the level that is concerned with features such as colour, loudness and texture.
- **Cinematic level:** This level is concerned with formal film and video editing techniques that are incorporated to produce expressive artifacts. For example, arranging a certain rhythmic pattern of shots to produce a climax, or introducing voice-over to shift the gaze.
- **Diegetic level:** This refers to the four-dimensional spatiotemporal world posited by a video image or a sequence of video images, including spatiotemporal descriptions of objects, actions, or events that occur within that world.
- **Connotative level:** This level of video semantics is the level of metaphorical, analogical and associative meanings that the objects and events in a video may have. An example of connotative significance is the use of facial expression to denote some emotion.

- **Subtextual level:** This is the level of more specialized, hidden and suppressed meanings of symbols and signifiers that are related to special cultural and social groups.

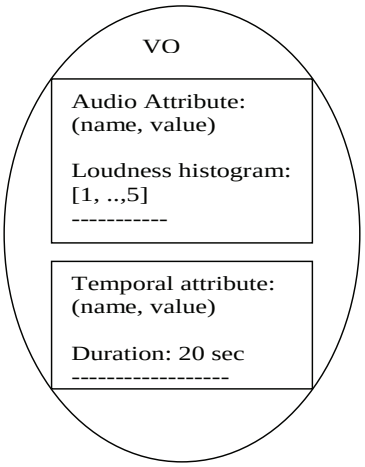
The main idea of this metamodel framework is to allow users to develop their own application models, based on their semantic notion and interpretation, by specifying objects and relationships of interest at any level of granularity.

Next we describe the data model to implement the ideas presented in the VIMET metamodel. The elements of the data model allow application (developers) to incrementally develop video semantics that needs to be modeled and represented in the context of the application domain.

VIDEO DATA MODEL

The main elements of the data model are: (i) Video Object (VO) to model a video sequence of any duration, (ii) VO Attributes that are either explicitly specified or based on automatically detected audio, visual, spatial and temporal features, (iii) VO Attribute-level relationships for computed attribute values, (iv) Video Concept Object (VCO) to accommodate fuzzy descriptions, and (v) Object level relationships, to support multimodal and multifeature relationships across video sequences.

Figure 2. A typical video object with two sets of attributes: audio and temporal



Video Object (VO)

We define a video object (VO) as an abstract object that models a video sequence at any level of abstraction in the semantic-temporal dimension shown in Figure 1. This is the most primitive object that can be used in a query.

Definition: A typical Video Object (VO) is a five-tuple

VO = <Xf, Sf, Tf, Vf , Af)

where

Xf is a set of textual attributes,
Sf is a set of spatial attributes,
Tf is a set of temporal attributes,
Vf is a set of visual attributes, and
Af is a set of audio attributes.

Xf represents a set of textual attributes that describe the semantics associated with the object at different levels of abstraction. This could be metadata or any textual description — a manual annotation of the content or about the content.

Sf represents spatial attributes that specify the spatial bounds of the object. This pertains to the space occupied by the object in a two-dimensional plane. This could be X and Y positions of the object or a bounding box of the object.

Ti represents the temporal attributes to describe the temporal bounds of the object. Temporal attributes includes start time, end time, and so forth. A time interval is a basic primitive used here.

Vf represents a set of attributes that characterize the object in terms of visual features. The values of these attributes are typically the result of visual feature extraction algorithms. Examples

of such attributes/features are colour histograms and motion vectors.

Af represents a set of attributes that characterize the object in terms of aural features. The values of these attributes are typically the result of audio analysis and feature extraction algorithms. Examples of such attributes/features are loudness curves and pitch values.

A typical video object — a video shot — is shown in Figure 2. The diagram shows a shot with temporal attribute duration and audio attribute loudness histogram. (To keep the diagram simple we have shown only a subset of possible attributes of a video object.) Each attribute has a value domain and is shown as a name value pair. For example, the audio attribute set has an audio attribute loudness whose value is given by a loudness histogram. Similarly, the temporal attribute set has an attribute duration whose value is given in seconds.

The applications determine the content of the video objects modeled. For example, a video object could be a frame in the temporal dimension, with an attribute specifying its location in the video. In the semantic dimension, the same frame could have visual features such as colour and texture histograms.

VO Attributes

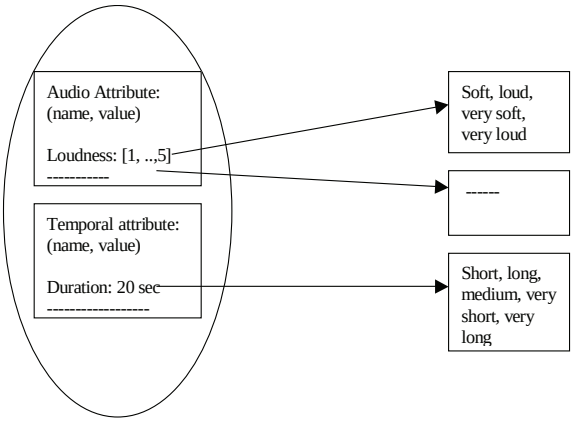
The attributes of a video object are either intensional or extensional. Extensional attribute values are text data, drawn from the character domain. The possible sources of extensional attributes are annotation, transcripts, keywords, textual description, terms from a thesaurus, and so forth. Extensional attributes fall in the feature category in Figure 1. Intensional attributes have specific value domains where the values are computed using appropriate feature extraction functions. Where the extensional attributes of the video objects are semantic in nature, relationships across such objects can be expressed as association, aggregation, and generalisation as per object-oriented or EER modeling methodologies. For intensional attributes, however, we need to establish specific relationships for each attribute type. For example, when we consider the temporal attribute whose value domain is "time-interval," we need to specify temporal relationships and corresponding operations that are valid over time intervals.

We define two sets of value domains for intensional attributes. The first set is the numerical domain and the second set is the linguistic domain. The purpose of providing a linguistic domain is to allow a fuzzy description of some attributes. For example, a temporal attribute duration could have a value equal to 20 (seconds) in the numerical domain. For the same temporal attribute, we define a second domain, which is a constrained set of linguistic terms such as "short," "long" and "very long." For this, we use a fuzzy linguistic framework, where the numerical values of duration are mapped to fuzzy terms such as short, long, and so forth. (Driankov et al., 1993). The fuzzy linguistic framework is defined as a four tuple <X, LX, QX, MX> where

- X = denotes the symbolic name of a linguistic variable (attributes in our case) such as duration.
- LX = set of linguistic terms that X can take such as "short," "long" and "very long.".
- QX = the numeric domain where X can take the values such as "time in seconds."
- MX = a semantic function which gives "meaning" to the linguistic terms by mapping X's values from LX to QX. The function MX depends on the types of attributes and the application domain. We defined one such function in Nepal et al. (2001).

Similarly, when we consider an audio attribute value based on the loudness histogram/curve, we map the numerical values to semantic terms such as "loud,", "soft," "very loud" and so on. By using a fuzzy linguistic framework, we are utilising

Figure 3. Mapping of numerical attribute values to fuzzy attribute values



the ability of the human to distinguish variations in audio and visual features. Figure 3 shows the mapping of a numerical attribute-value domain to a linguistic attribute-value domain.

VO Attribute-Level Relationships

Relationships across video objects can be defined at two levels: the object and attribute levels. We will discuss the object level relationships in a later section. Here we discuss attribute-level relationships to illustrate the capabilities of the data model. Each intensional attribute value allows us to define relationships that are valid for that particular attribute-value domain. For example, when we consider visual relationships based on the "brightness" attribute, we should be able to establish relationships such as "brighter-than," "dimmer-than," and "similar" by grouping light intensity values. By exploiting such attribute-level relationships across each intensional attribute, it is possible to establish a multidimensional relationship between video objects. Here each dimension reflects a perceivable variation in the computed values of the relevant intensional attribute.

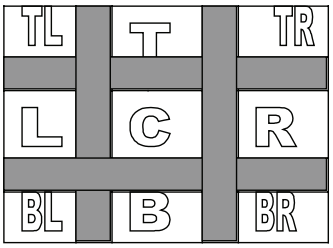
Table 1 shows an illustrative set of attribute-level relationships. The relationship values are drawn from a predefined constrained set of relationships valid for a particular attribute type. A typical relationship value set for brightness is {brighter-than, dimmer-than, similar}. Each relationship in the set is given a threshold based on the eye's ability to discriminate between light intensity levels. The fuzzy scale helps in accommodating subjectivity at the user level.

Next we give some examples of directional relationships used for spatial reasoning in large-scale spaces, that is, spaces that cannot be seen or understood from a single point of view. Such relationships are useful in application areas such as Geographical Information Systems. In the case of video databases, it is more meaningful to define equivalent positional relationships as we are dealing with spaces within a frame that can be viewed from a point. The nine positional relationships are given by AP = {Top, TopLeft, Left, BottomLeft, Bottom, BottomRight, Right, TopRight, Centre} as shown in Figure 4. These nine relationships can be used as linguistic values for a spatial attribute "position" given by a bounding box. Similarly, appropriate linguistic terms can be developed for other attributes as shown in Table 1.

Table 1. Attribute-level relationships

Attribute	*Relationship Type*	*Relationship Value set*
Brightness	Visual, based on light intensity	{Brighter, Dimmer, Similar}
Contrast	Visual, based on contrast measures	{Higher, Lower, Similar}
Color	Visual, based on color	(Same, Different, Resembles}
Loudness	Audio, based on sound level	{Louder, Softer, Similar}
Pitch	Audio, based on pitch	{Higher, Lower, Similar}
Size	Visual, based on size	{Bigger, Smaller, Similar}
Duration	Temporal, based on duration	{Shorter, Longer, Equal}

Figure 4. Positional relations in a two-dimensional space



Video Concept Object

In order to support the specification of an attribute relationship (using linguistic terms), we define a video concept object. A Video Concept Object (VCO) is a video object with a semantic attribute value attached to each intensional attribute. The main difference between a VO and a VCO lies in the domain of the intensional attributes. The attributes of a VO have numerical domains, and the attributes of VCO have a domain which is a set of linguistic terms which forms a domain for semantic attribute value. The members of this set are controlled vocabulary terms that reflect the (fuzzy) semantic value for each attribute type. The domain set will be different for audio, visual, temporal and spatial attributes.

Definition: A typical Video Concept Object (VCO) is a five-tuple

VCO = <Xc, Sc, Tc, Ac, Vc>

where

Xc is a set of textual attributes that define a concept, the attribute values are drawn from the character domain,

Sc represents a set of spatial attributes. The value domain is a set of (fuzzy) terms that describe relative positional and directional relationships,

Tc represents a set of temporal attributes whose values are drawn from a set of fuzzy terms used to describe time interval or duration.

Ac represents a set of audio attributes (an example is loudness attribute whose values are drawn from a set of fuzzy terms that describe loudness).

Vc represents a visual attribute whose values are drawn from a set of fuzzy terms that describe that particular visual attribute.

The relationship between a VO and a VCO is established using fuzzy linguistic mapping as shown in Figure 5.

In a fuzzy linguistic model, attribute name-relationship pair is equivalent to fuzzy variable-value pair. In general, a user can query and retrieve video from a database using any primitive VO/VCO. An example is "retrieve all videos where an object A is at the right-bottom of the frame." In this example, the expressive power of a query is based on a single attribute-value and is limited. A more interesting query would be "retrieve all video sequences where the loudness value is very high and the duration of the sequence is short." Such queries would include VCOs and VOs.

VO and VCO Relationships

In order to retrieve sequences with multiple relationships over different VOs and VCOs, we need appropriate operators. In addition, we need some kind of knowledge or heuristic rule(s) that help us interpret these relationships. This motivates us to define a Video Semantics System.

Definition: A typical Video Semantics System (VSS) is a five-tuple

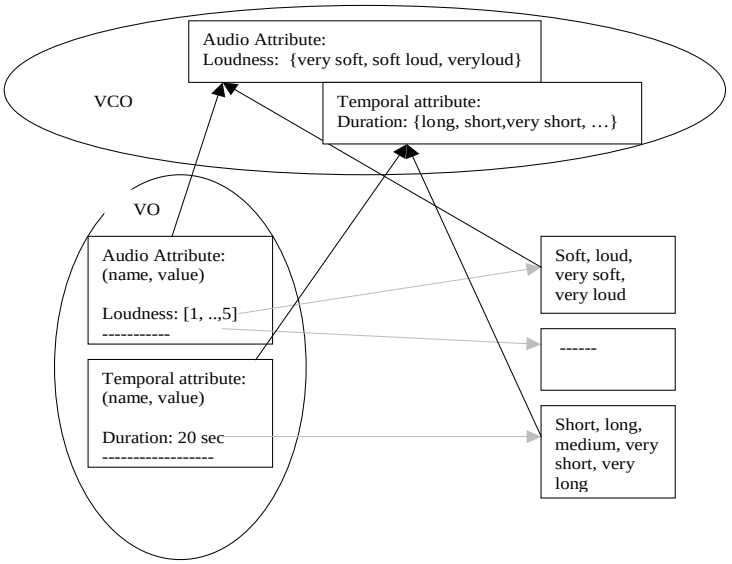
VSS = < VO/VCO, Sro, Tro, Fro, I>

where

VO/VCO is a set of Video Objects or Video Concept Objects,

Sro is a set of spatial relationship operators,

Figure 5. An example VCO derived using a fuzzy linguistic model



Tro is a set of temporal relationship operators, and
Fro is a set of multimodal operators.
I is an interpretation model of the video object.

Next we describe some operators and interpretation models. We define spatial operators for manipulating relationships of objects over spatial attributes. This helps in describing the structure of features (Figure 1). We define temporal operators for manipulating relationships over temporal attributes. This helps to describe order of events (Figure 1). For multimodal multifeature composition, however, we define fuzzy Boolean operators.

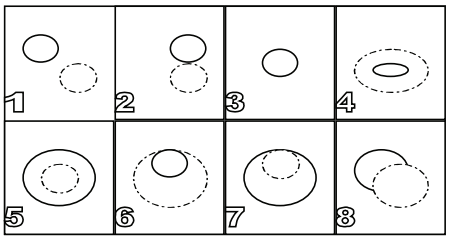
Spatial Relationship Operators (SROs)

A number of spatial relationships with corresponding operators have been proposed and used in spatial databases, geographical information systems and multimedia database systems. We describe them into the following categories. It is important to note that SROs are valid only if the VO has attributes (values) that indicate spatial bounds.

- **Topological Relations:** Topological relations are spatial relations that are invariant under bijective and continuous transformations that have also continuous inverses. Topological equivalence does not necessarily preserve distances and directions. Instead, topological notions include continuity, interior, and boundary, which are defined in terms of neighbourhood relations. The eight topological relationship operators are given as TR = {Disjoint, Meet, Equal, Inside, Contains, Covered_By, Covers, Overlap} (Egenhofer & Franzosa, 1991) as shown in Figure 6. These relationship operators are binary.
- **Relative Positional Relations:** The relative positional relationship operators are given by RP = {Right of, Left of, Above, Below, In front of, Behind}. These operators are used to express the relationships among VCOs. These relative positional relationship operators are binary.

Sro = TR ∪ RP

Figure 6. Examples of eight basic topological relationships



Temporal Relationship Operators (TROs)

As a video is a continuous medium, temporal relations provide important cues for video data retrieval. Allen (1983) has defined 13 temporal interval relations. Many variations of Allen's temporal interval relations have been proposed and used in temporal and multimedia databases. These relations are used to define the temporal relationships of events within a video. For example, weather news appears after the sports news in a daily TV news broadcast. It is important to note that TROs are valid only for VOs that have attributes with temporal bounds. The 13 temporal relationships defined by Allen are given by TR = {Before, Meets, Overlaps, Finishes, Starts, Contains, Equals, During, Started by, Finished by, Overlapped by, Met by, After}. (Note: This set TR corresponds to the set of temporal relationship operators defined as Tro in VSS.)

Multimodal Operators

Traditionally the approach used for audiovisual content retrieval is based on similarity measures on the extracted features. In such systems, users need to be familiar with the underlying features and express their queries in terms of these (low-level) features. In order to allow users to formulate semantically expressive queries, we define a set of fuzzy terms that can be used to describe a feature using fuzzy attribute relationships. For example, when we are dealing with the "loudness" feature, we use a set of fuzzy terms such as "very loud," "loud," "soft," and "very soft" to describe the relative loudness at the attribute level. This fuzzy measure is described at the VCO level. A query on VSS, however, can be multimodal in nature and involve many VCOs. In order to have a generic way to combine multimodal relationships, we use simple fuzzy Boolean operators. The fuzzy Boolean operator set is given by

FR = {AND, OR, NOT}.

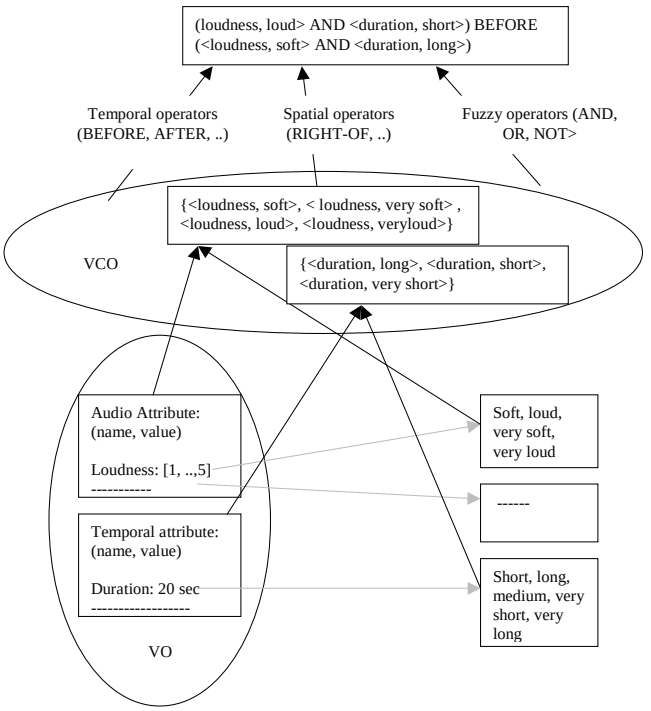
(Note: This set FR corresponds to the set of multimodal relationship operators defined as Fro in VSS.)

An example of a multimodal, multifeature query is shown in Figure 7.

Interpretation Models

In the third section we identified five different levels of cinematic codification and description that help us interpret the "meaning" of a video. Lindley and Srinivasan (1998) have demonstrated empirically that these descriptions are meaningful in capturing distinctions in the way images are viewed and interpreted by a nonspecialist audience, and between this audience and the analytical terms used by filmmakers and film critics. Modeling "the meaning" of a video, shot, or sequence requires the description of the video object at any or all of the interpretation levels described in the third section. Interpretation Models can be based on one or several of these five levels. A model based on perceptual visual characteristics is the subject of a large amount of current research on video content-based retrieval (Ahanger & Little, 1996). Models based on cinematic constructs incorporate the expressive artifacts such as camera operations (Adam et al., 2000), lighting schemes and optical effects (Truong et al., 2001). Automated detection of cinematic features is another area of vigorous current research activity (see

Figure 7. An example of multimodal query using fuzzy and temporal operators on VCOs



Ahanger & Little). While modeling at the diegetic level the basic perceptual features of an image are organised into a four-dimensional spatiotemporal world posited by a video image or sequence of video images. This includes the spatiotemporal descriptions of agents, objects, actions and events that take place within that world. The interpretation model that we illustrate in the fifth section is a diegetic model based on interpretations at the perceptual level. Examples of connotative meanings are the emotions connoted by actions or the expressions on the faces of characters. The subtextual level of interpretation involves representing specialised meanings of symbols and signifiers. For both the connotative and the subtextual levels, definitive representation of the "meaning" of a video is in principle impossible. The most that can be expected is an evolving body of interpretations.

In the next section we show how a user/author can develop application semantics by explicitly specifying objects and relationships and interpretation models. The ability to create different models allows users/authors to contextualise the content to be modeled.

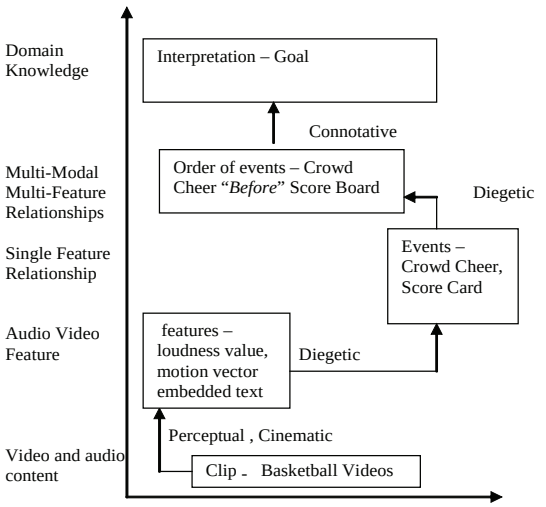
EXAMPLE

Here we illustrate the process of developing a specific application model to describe video content at different semantic levels. The process is incremental, where the different elements of the VIMET framework are used to retrieve "goal" segments from basketball videos. Here we have used a top-down approach to modeling, where we first developed the interpretation models from an empirical investigation of basketball videos (Nepal et al., 2001). We then develop an object model for the application.

Figure 8 shows an instantiation of the metamodel.

The observation of television broadcasts of basketball games gave some insights into com-

Figure 8. An instance of metamodel for a video semantic "Goal" in basketball videos using temporal interpretation model I



monly occurring patterns of events perceived during the course of a basketball game. We have considered a subset of these as key events that occur repeatedly throughout the video of the game to develop a temporal interpretation model. They were: crowd cheer, scorecard display and change in players' direction. We then identified the audio-video features that correspond to the key events — manually observed. The features identified include energy levels of audio signals, embedded text regions, and change in direction of motion. Since the focus of this chapter is on building a video semantic "goal," we will not elaborate on the feature extraction algorithms in detail. We used the MPEGMaaate audio analysis toolkit (MPEG MAAATE, 2000) to identify "high-energy" segments from loudness values. Appropriate thresholds were applied to these high-energy segments to capture an event "crowd cheer." The mapping to crowd cheer expresses a simple domain heuristic (diegetic and connotative interpretation) for sports video content. Visual feature extraction consists of identifying embedded text (Gu, 1998) and is mapped to score card displays in the sports domain. Similarly, camera pan (Srinivasan et al., 1997) motion is extracted and used to capture change in players' direction. The next level of semantics is developed by exploring the temporal order of events such as crowd cheer and scorecard displays. Here we use temporal interpretation models that show relationships on multiple features from multiple modalities.

Interpretation Models

We observed basketball videos and developed five different temporal interpretation models, as follows.

Model I

This model is based on the first key event — crowd cheer. Our observation shows that there is a loud cheer within three seconds of scoring a legal goal. Hence, in this model, the basic diegetic interpretation is that a loud cheer follows every legal goal, and a loud cheer only occurs after a legal goal. The model T1 is represented by

T1: Goal $\rightarrow$ [3 sec] $\rightarrow$ crowd cheer

Intuitively, one can see that the converse may not always be true, as there may be other cases where a loud cheer occurs, for example, when a streaker runs across the field. Such limitations are addressed to some extent in the subsequent models.

Model II

This model is based on the second key event— scoreboard display. Our observation shows that the scoreboard display is updated after each goal. Our cinematic interpretation in this model is that a scoreboard display appears (usually as embedded text) within 10 seconds of scoring a legal goal. This is represented by the model T2.

T2: Goal → [10 sec] → Scoreboard

The limitation of this model is that the converse here may not always be true, that is, a scoreboard display may not always be preceded by a legal goal.

Model III

This model uses a combination of two key events with a view to address the limitations of T1 and T2. As pointed out earlier, all crowd cheers and scoreboard displays may not always indicate a legal goal. Ideally when we classify segments that show a shooter scoring goals, we need to avoid inclusion of events that do not show a goal, even though there may be a loud cheer. In this model, this is achieved by temporally combining the scoreboard display with crowd cheer. Here, our diegetic interpretation is that every goal is followed by crowd cheer within three seconds, and by a scoreboard display within seven seconds after the crowd cheer. This discards events that have crowd cheer, but no scoreboard and events that have scoreboards, but no crowd cheer.

T3: Goal → [3 sec] → Audio Cheer → [7 sec] → Score Board

Model IV

This model addresses the strict constraints imposed in Model 3. Our observations show that while the pattern shown in three is valid most of the times, there are cases where the field goals are accompanied by loud cheers and no scoreboard display. Similarly, there are cases where goals are followed by scoreboard displays but not crowd cheer, as in the case of free throws. In order to capture such scenarios, we have used a combination of models I and II and proposed a model IV.

T4: T1 → T2

where ∪ is the union of results from models H1 and H2.

Model V

While model IV covers most cases of legal goals, due to the inherent limitations pointed out in models I and II, model IV could potentially classify segments where there are no goals. Our observations show that Model IV captures the maximum number of goals, but it also identifies many nongoal segments. In order to retain the number of goal segments and still remove the nongoal segments, we introduce the third key event — change in direction of players. In this model, if a crowd cheer appears within 10 seconds of a change in direction, or a scoreboard appears within 10 seconds of a change in direction, there is likely to be a goal within 10 seconds of the change in direction. This is represented as follows.

T5: Goal → [10 secs] → Change in direction → [10secs] → Crowd cheer

OR

T5:Goal → [10 secs] → Change in direction → [10secs] → Scoreboard

Although, in all models, the time interval between two key-events is hardwired, the main idea is to provide a temporal link between key-events to build up high-level semantics.

Object Model

For the interpretation models described above, we combine video objects characterized by different types of intensional attributes to develop new video objects or video concept objects. An instance of video data model is shown in Figure 9. For example, we use the "loudness" feature and a temporal feature to develop a new video concept object called "crowd cheer". For example, we first define video semantics crowd cheer as.

Figure 9. An instance of the data model for an example explained in this section.

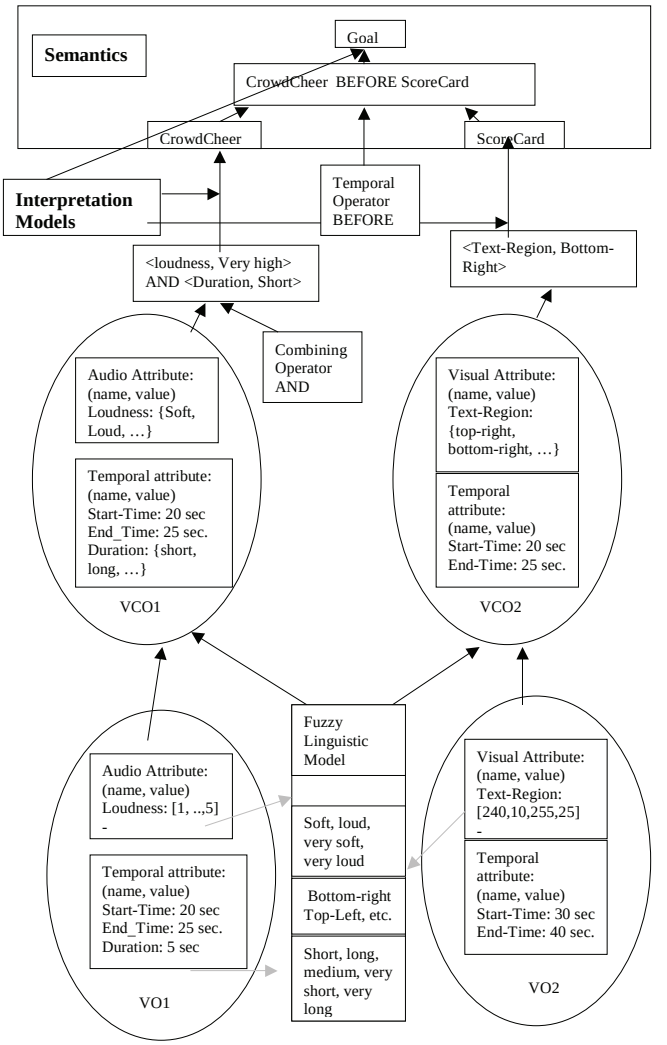


Table 2. A list of data sets used for our experiments and the results of our observations

Games	*Description*	*Length*	*Number of Cheers*	*Number of Scoreboard Displays*	*Number of Goals*	*Number ofchanges in direction of players' movements*
A	Australia Vs Cuba 1996 (Women)	00:42:00	31	49	52	74
B	Australia Vs USA 1994 (Women)	00:30:00	27	46	30	46
C	Australia Vs Cuba 1996 (Women)	00:14:51	16	16	17	51
D	Australia Vs USA 1997 (Men)	00:09:37	13	16	18	48

Table 3. A summary of results of automatic evaluation of various algorithms

Clips	Total number of baskets (relevant)	Algorithms	Total (retrieved)	Correct Decision (relevant ∩ retrieved)	Precision (%)	Recall (%)
C	17	T1	15	12	80	70.50
		T2	20	15	75	88.23
		T3	11	11	100	64.70
		T4	24	16	66.66	94.1
		T5	17	15	88.23	88.23
D	18	T1	16	11	68.75	61.11
		T2	19	17	89.47	94.44
		T3	10	10	100	55.55
		T4	25	18	72.0	100
		T5	22	16	72.72	88.88

```
DEFINE CrowdCheer AS
SELECT V1.Start-time, V1.End-time
FROM VCO V1
WHERE <V1.Loudness, Very-high> AND
        <V1.Duration, Short>
```

Here we use diegetic knowledge about the domain to interpret a segment where a very high loud value appeared for a short duration as a crowd cheer. Similarly, we can define scorecard as follows.

```
DEFINE ScoreCard AS
SELECT V2.Start-time, V2.End-time
FROM VCO V2
WHERE  <V2.Text-Region, Bottom-Right>
```

We then use the temporal interpretation model to build a query to develop a video concept object that represents a "goal" segment. This is defined as follows:

```
DEFINE Goal AS
SELECT [10]  MIN(V1.Start-time, V2.Start-
time),
        MAX(V1.End-time, V2.End-time)
FROM CrowdCheer V1, ScoreCard V2
WHERE V1 BEFORE V2
```

Here the query returns the 10 best-fit video sequences that satisfy the query criteria - goal.

We have implemented this application model for basketball videos. Implementing such a model necessarily involves developing appropriate interpretation models, which is a labour-intensive task. The VIMET framework helps this process by facilitating incremental descriptions of video content.

We now present an evaluation of the interpretation models outlined in the previous section.

Evaluation of Interpretation Models

The data set used to evaluate the different temporal models for building a video semantic "goal" in basketball videos is shown in Table 2. The first two clips A and B are used for evaluating observations and the last two clips are used for evaluating automatic analysis.

The standard precision-recall method was used to compare our automatically generated

goal segments with the ones manually judged by humans.

Precision is the ratio of the number of relevant clips retrieved to the total number of clips retrieved. The ideal situation corresponds to 100% precision, when all retrieved clips are relevant.

$$precision = \frac{|\ relevant \cap retrieved\ |}{|\ retrieved\ |}$$

Recall is the ratio of the number of relevant clips retrieved to the total number of relevant clips. We can achieve ideal recall (100%) by retrieving all clips from the data set, but the corresponding precision will be poor.

$$recall = \frac{|\ relevant \cap retrieved|}{|\ relevant|}$$

We evaluated the temporal interpretation models in our example data set. The manually identified "legal goals" (which include field goals and free throws) of the videos in our data set are shown in column 2 in Table 3.

The result of automatic analysis shows that the combination of all three key events performs much better with high recall and precision values (~88%). In model T1, the model correctly identifies 12 goal segments out of 17 for video C and 11 out of 18 for video D. However, the total number of crowd segments detected by our crowd cheer detection algorithm is15 and 16 for videos C and D, respectively. That is, there are few legal goal segments that do not have crowd cheer and vice versa. Further analysis shows that crowd cheer events resulting from other interesting events such as "fast break", "clever steal" and "great check or screen" gives false positive results. We observed that most of the field goals are accompanied by crowd cheer. However, many goals scored by free throws are not accompanied by crowd cheer. We also observed that in certain cases lack of supporters among the spectators for a team yield false negative results. In model T2, the model correctly identifies 15 goals out of 17 in video C and 17 out of 18 in video D. Our further analysis confirmed that legal goals due to free throws are not often accompanied by scoreboard displays, particularly when the scoreboard is updated at the end of free throws rather than after each free throw. Similarly, our feature extraction algorithm used for scoreboard not only detects scoreboards but also other textual displays such as team coach names and the number of fouls committed by a player. Such textual features increase the number of false positive results. We plan to use the heuristics developed here to improve our scoreboard detection algorithm in the future. The above discussion is valid for algorithms T3, T4 and T5 as well.

CONCLUDING REMARKS

Emerging new technologies in video delivery such as streaming over the Internet have made video content a significant component of the information space. Video content holders now have an opportunity to provide new video products and services by reusing their video collections. This requires more than content-based analysis systems.

We need effective ways to model, represent and describe video content at several semantic levels that are meaningful to users of video content. At the lowest level, content can be described using low-level features such as colour and texture, and at the highest-level the same content can be described using high-level concepts. In this chapter, we have provided a systematic way of developing content descriptions at several semantic levels. In the example in the fifth section, we have shown how (audio and visual) feature extraction techniques can be effectively used together with interpretation models, to develop higher-level semantic descriptions of content. Although the example is specific to the sports genre, the VIMET framework and the associated data model provides a platform to develop several descriptions of the same video content, depending on the interpreta-

tion level of the annotator. The model supports one of the mandates of MPEG-7 by supporting content descriptions, to accommodate multiple interpretations.

Chapter 7.7
Perceptual Multimedia:
A Cognitive Style Perspective

Gheorghita Ghinea
Brunel University, UK

Sherry Y. Chen
Brunel University, UK

ABSTRACT

In this chapter, we describe the results of empirical studies which examined the effect of cognitive style on the perceived quality of distributed multimedia. We use two dimensions of Cognitive Style Analysis, Field Dependent/Independent and Verbaliser/Visualiser, and the Quality of Perception metric to characterise the human perceptual experience. This is a metric which takes into account multimedia's infotainment (combined informational and entertainment) nature, and comprises not only a human's subjective level of enjoyment with regards to multimedia content quality, but also his/her ability to analyse, synthesise and assimilate the informational content of such presentations. Results show that multimedia content and dynamism are strong factors influencing perceptual quality.

INTRODUCTION

Multimedia has been identified as a potential method of improving the learning process in particular and the user computing experience in general. Its use encourages user interaction, thus ensuring that users cannot become a passive participant of the learning experience (Neo & Neo, 2004). Not only does the use of multimedia in applications increase interaction levels, but increases interest, motivation, and retention of information (Demetriadis, Triantafilou, & Pombortis, 2003). Moreover, the fact that students seem to prefer the use of multimedia for teaching to the standard teacher-student paradigm as it is more user-centred (Zwyno, 2003), comes as no surprise. The potential of multimedia has, to date, not been fully realised. Users perceive, process, and organise information in individualistic ways, yet current multimedia applications routinely fail to take this into consideration (Stash, Cristea, & De Bra, 2004).

We therefore believe that the effectiveness of a multimedia presentation would be hindered if it did not include the user experience in terms of enjoyment and information assimilation. Key to this is the issue of the quality of the multimedia presentation. Quality, in our perspective, has two main facets in a distributed multimedia environ-

ment: of service and of perception. The former, Quality of Service (QoS), illustrates the technical side of computer networking and represents the performance properties that the underlying network is able to provide. The latter, Quality of Perception (QoP), characterises the perceptual experience of the user when interacting with multimedia applications. While the quality delivered by communication networks has traditionally been measured using QoS metrics, we believe that, as users are "consumers" of multimedia applications, it is their opinions about the quality of multimedia material visualised which ultimately measures the success (or indeed, failure) of such applications to deliver desktop instruction material. When this delivery is done over Wide Area Networks such as the World Wide Web ("the Web"), transmission of multimedia data has to accommodate not only user subjective preferences, but also fluctuating networking environments.

The other concern is whether distributed multimedia presentations can accommodate individual differences. Previous studies indicate that users with different characteristics have different perceptions of multimedia presentation (Chen & Angelides, 2003). In particular, different cognitive style groups benefit from different types of multimedia presentation. Therefore, empirical evaluation that examines the impact of cognitive styles becomes paramount because such evaluations can provide concrete prescriptions for developing learner-centred systems that can match the particular needs of each cognitive style group. While QoP has been investigated in the context of distributed multimedia quality (Ghinea & Thomas, 2005), the study did not take into account the possible effect of users' cognitive styles on their QoP.

In this chapter, we present the results of studies which looked at how multimedia content is perceived by different cognitive style groups. Accordingly, the chapter begins by building a theoretical background to present previous work in the area of subjective distributed multimedia quality and to discuss the influence of cognitive style on user perception of multimedia presentations. It then describes and discusses the findings of our empirical studies. The chapter ends with conclusions being drawn, highlighting the value of integrating QoP considerations with users' cognitive styles in the delivery of distributed multimedia presentations.

THEORETICAL BACKGROUND

Quality of Service

The networking foundation on which current distributed multimedia applications are built either do not specify QoS parameters (also known as best effort service) or specify them in terms of traffic engineering parameters such as delay, jitter, and loss or error rates. However, these parameters do not convey application-specific needs such as the influence of clip content and informational load on the user multimedia experience.

Furthermore, traditional approaches of providing QoS to multimedia applications have focused on ways and means of ensuring and managing different technical parameters such as delay, jitter, and packet loss over unreliable networks. To a multimedia user, however, these parameters have little immediate meaning or impact. Although (s)he might be slightly annoyed at the lack of synchronisation between audio and video streams, it is highly unlikely that (s)he will notice, for instance, the loss of a video frame out of the 25 which could be transmitted during a second of footage, especially if the multimedia video in question is one in which the difference between successive frames is small. Moreover, in a distributed setting, the underlying communication system will not be able to provide an optimum QoS due to two competing factors, multimedia data sizes and network bandwidth. This results in phenomena such as congestion, packet loss, and errors. However, little work has

been reported on the relationship between the network provided QoS and the satisfaction and perception of the user.

While the QoS impacts upon the perceived multimedia quality in distributed systems, previous work examining the influence of varying QoS on user perceptions of quality has almost totally neglected multimedia's infotainment quality (i.e., a mixture of both of informational as well as entertainment content), and has concentrated primarily on the perceived entertainment value of presentations displayed with varying QoS parameters.

Accordingly, previous work has studied the impact of varying clip frame rates on the user's enjoyment of multimedia applications (Apteker, Fisher, Kisimov, & Neishlos, 1995; Fukuda, Wakamiya, Murata, & Miyahara, 1997), and it has been shown that the dependency between human satisfaction and the required bandwidth of multimedia clips is non-linear. Consequently, a small change in human receptivity leads to a much larger relative variation of the required bandwidth. From a different perspective, Wijesekera and Srivastava (1996) and Wijesekera, Srivastava, Nerode, and Foresti (1999) have examined the effect that random media losses have on the user-perceived quality. Their work showed that missing a few media units will not be negatively perceived by a user, as long as too many such units are not missed consecutively and that this occurrence is infrequent. Moreover, because of the bursty nature of human speech (i.e. talk periods interspersed with intervals of silence), audio loss is tolerated quite well by humans as it results merely in silence elimination (21% audio loss did not provoke user discontent (Wijesekera et al., 1999). However, viewer discontent for aggregate video losses increases gradually with the amount of losses, while for other types of losses and synchronisation defects, there is an initial sharp rise in viewer annoyance that afterwards plateaus out.

Further work has been undertaken by Steinmetz (1996) who explored the bounds within which lip synchronisation can fluctuate without undue annoyance on the viewer's part, while the establishment of metrics for subjective assessment of teleconferencing applications was explored in Watson and Sasse (1996). Indeed, the correlation between a user's subjective ratings of differing-quality multimedia presentation and physiological indicators has been studied by Wilson and Sasse (2000). However, research has largely ignored the influence that the user's psychological factors have on the perceived quality of distributed multimedia.

The focus of our research has been the enhancement of the traditional view of QoS with a user-level defined QoP. This is a measure that encompasses not only a user's satisfaction with multimedia clips, but also his/her ability to perceive, synthesise, and analyse the informational content of such presentations. As such, we have investigated the interaction between QoP and QoS and its implications from both a user perspective as well as from a networking angle.

Table 1. The differences between field-dependent and field-independent learners (Adapted from Jonassen & Grabowski, 1993; Riding & Rayner, 1998)

Field Dependent Learners	Field Independent Learners
They are externally directed and are easily influenced by salient features.	They are internally directed and process information with their own structure.
They experience surroundings in a relatively global fashion and struggle with individual elements.	They experience surroundings analytically and are good with problems that require taking elements out of their whole context.
They are more likely to accept ideas as presented.	They are more likely to accept ideas only strengthened through analysis.

Cognitive Styles

Cognitive style is an individual's characteristic and consistent approach to organising and processing information. Riding and Rayner (1998) defined cognitive style as "an individual preferred and habitual approach to organising and representing information" (p.25). Among a variety of cognitive styles, Field Dependence/Independence and Visualiser/Verbaliser are related to perceptual multimedia. The former concerns how users process and organise information, whereas the latter emphasises on how users perceive the presentation of information.

Field Dependence/Independence is related to the "degree to which a learner's perception or comprehension of information is affected by the surrounding perceptual or contextual field" (Jonassen & Grabowski, 1993, p. 87). Field-dependent people tend to perceive objects as a whole, whereas Field -independent people focus more on individual parts of the object. Field-dependent individuals rely more on external references; by contrast, field-independent individuals rely more on internal references (Witkin, Moore, Goodenough, & Cox, 1977). The differences between field-independent and field-dependent users are summarized in Table 1.

The main difference between visualiser/verbaliser focuses on a preference for learning with words versus pictures. A visualiser would prefer to receive information via graphics, pictures, and images, whereas a verbaliser would prefer to process information in the form of words, either written or spoken (Jonassen & Grabowski, 1993). In addition, visualisers prefer to process information by seeing, and they will learn most easily through visual and verbal presentations, rather than through an exclusively verbal medium. Moreover, their visual memory is much stronger than their verbal. On the other hand, verbalisers prefer to process information through words, and find they learn most easily by listening and talking (Laing, 2001). Their differences are summarised in Table 2.

These two dimensions of cognitive styles have been investigated by several works in learning environments. For example, a study by Chuang (1999) produced four-courseware versions: animation+text, animation+voice, animation+text+voice, and free choice. The result showed that field-independent subjects in the animation+text+voice group or in the free choice group scored significantly higher than those did in the animation+text group or in the animation+voice group. No significant presentation effect was found for the field-dependent subjects. Furthermore, Riding and Douglas (1993), with 15-16-year-old students, found that the computer-presentation of material on motorcar braking systems in a Text-plus-Picture format facilitated the learning by visualisers compared with the same content in a Text-plus-Text version. They further found that in the recall task in the Text-plus-Picture condition, 50% of the visualisers used illustrations as part of their answers, compared to only 12% of the verbalisers. Generally, visualisers learn best from pictorial presentations, while verbalisers learn best from verbal presentations. However, paucity of study investigates the relationship between the use patterns of these two dimensions of cognitive styles in multimedia systems in general, and specifically in distributed multimedia systems, where quality

Table 2. The differences between visualisers and verbalisers (Adapted from Jonassen & Grabowski, 1993; Riding & Rayner, 1998)

Visualisers	Verbalisers
Think concretely	Think abstractly
Have high imagery ability and vivid daydreams	Have low imagery ability
Like illustrations, diagrams, and charts	Like reading text or listening
Prefer to be shown how to do something	Prefer to read about how to do something
Are more subjective about what they are learning	Are more objective about what they are learning

fluctuations can occur owing to dynamically varying network conditions. As the QoP metric is one which has an integrated view of user-perceived multimedia quality in such distributed systems, it is of particular interest to investigate the impact of cognitive styles on QoS-mediated QoP, as it will help in achieving a better understanding of the factors involved in such environments (distance learning and CSCW, to name but two) and ultimately help in the elaboration of robust user models which could be used to develop applications that meet with individual needs.

METHODOLOGY DESIGN

Overview

This chapter reports the results of studies which investigated how different multimedia content is perceived by different cognitive style dimensions. Perceived multimedia quality was examined using the QoP measure, the only such metric that takes into account multimedia's infotainment duality.

Measuring QoP

As previously mentioned, QoP has two components: an information analysis, synthesis, and assimilation part (henceforth denoted by *QoP-IA*) and a subjective level of enjoyment (henceforth denoted by *QoP-LOE*). To understand QoP in the context of our work, it is important to explain how both these components were defined and measured.

Measuring Information Assimilation (QoP-IA)

In our approach, QoP-IA was expressed as a percentage measure, which reflected a user's level of information assimilated from visualised multimedia content. Thus, after watching a particular multimedia clip, the user was asked a standard number of questions (10, in our case) which examined information being conveyed in the clip just seen, and QoP-IA was calculated as being the proportion of correct answers that users gave to these questions. All such questions asked must, of course, have definite answers, for example: (from the Rugby video clip used in our experiments) "What teams are playing?" had an unambiguous answer (England and New Zealand) which had been presented in the multimedia clip, and it was therefore possible to determine if a participant had answered this correctly or not.

Thus, by calculating the percentage of correctly-absorbed information from different information sources, it was possible to determine from which information sources participants absorbed the most information. Using this data, it is possible to determine and compare, over a range of multimedia content, potential differences that might exist in QoP-IA.

Measuring Subjective Level of Enjoyment (QoP-LOE)

The subjective level of enjoyment (QoP-LOE) experienced by a user when watching a multimedia presentation, was polled by asking users to express, on a scale of 1-6, how much they enjoyed the presentation (with scores of 1 and 6 respectively representing "no" and "absolute" user satisfaction with the multimedia video presentation).

In keeping with the methodology followed by Apteker et al (1995), users were instructed not to let personal bias towards the subject matter in the clip or production-related preferences (for instance, the way in which movie cuts had been made) influence their enjoyment quality rating of a clip. Instead, they were asked to judge a clip's enjoyment quality by the degree to which they, the users, felt that they would be satisfied with a general purpose multimedia service of such quality. Users were told that factors which should influence their quality rating of a clip included clarity and acceptability of audio sig-

nals, lip synchronisation during speech, and the general relationship between visual and auditory message components. This information was also subsequently used to determine whether ability to assimilate information has any relation to user level of enjoyment, the second essential constituent (beside information analysis, synthesis, and assimilation) of QoP.

Participants

This chapter brings together the results of two empirical studies conducted at Brunel University's School of Information Systems, Computing, and Mathematics. In the first study, participants' cognitive styles were categorised according to the Field Dependent/Independent dimension, while in the second, participants' cognitive styles were categorised using the Verbaliser/Visualiser dimension.

Experiment 1

Sixty-six subjects participated in this study. Despite the fact that the participants volunteered to take part in the experiment, they were extremely evenly distributed in terms of cognitive styles, including 22 field-independent users, 22 intermediate users, and 22 field-dependent users. In terms of gender, there were 34 male users and 32 female users.

Experiment 2

This study involved 71 participants, which turned out to be quite evenly distributed in terms of cognitive styles, including 23 field-independent users, 25 intermediate users, and 23 field- dependent users. Moreover, participant breakdown according to gender was also quite evenly matched (37 males and 34 females). For both studies, all participating

users were inexperienced in the content domain of the multimedia video clips visualised as part of our experiments, which will be described next.

Research Instruments

Video Clips

A total of 12 video clips were used in our study. The multimedia clips were visualised under a Microsoft Internet Explorer browser with a Microsoft Media player plug-in, with users subsequently filling in a Web-based questionnaire to evaluate QoP for each clip.

These 12 clips had been used in previous QoP experiments (Ghinea & Thomas, 1998), and were between 30-44 seconds long and digitised in MPEG-1 format. The subject matter they portrayed was varied (as detailed in Table 3 and Figure 1) and taken from selected television programmes, thereby reflecting informational and entertainment sources that average users might encounter in their everyday lives. Thus, six of the clips (2, 5, 6, 7, 8, and 12 in Table 1) comprised predominantly informational content, with the remainder of the clips being viewed mainly for entertainment purposes. Also varied was the dynamism of the clips (i.e., the rate of change between the frames of the clip), which ranged from a relatively static news clip to a highly dynamic space action movie. Table 3 also describes the importance, within the context of each clip, of the audio, video, and textual components as purveyors of information, as previously established through user tests (Ghinea & Thomas, 1998).

Cognitive Style Analysis

The cognitive style dimensions investigated in this study include Field Dependence/Independence and Verbaliser/Visualiser. A number of instruments have been developed to measure these two dimensions. Riding's (1991) Cognitive Style Analysis (CSA) was applied to identify each participant's cognitive styles in this study, because the CSA offers computerised administration and scoring. In addition, the CSA can offer various English versions, including Australasian, North American, and United Kingdom contexts.

The CSA uses two sub-tests to identify Field Dependence/Independence. The first presents items containing pairs of complex geometrical figures that the individual is required to judge as either the same or different. The second presents items each comprising a simple geometrical shape, such as a square or a triangle, and a complex geometrical figure, as in the GEFT, and the individual is asked to indicate whether or not the simple shape is contained in a complex one by pressing one of two marked response keys (Riding & Grimley, 1999).. The first sub-test is a task requiring field-dependent capacity. Conversely, the second sub-test requires the disembedding capacity associated with field-independence.

The CSA uses two types of statement to measure the Verbal-Imagery dimension and asks participants to judge whether the statements are true or false. The first type of statement contains information about conceptual categories while the second describes the appearance of items. There are 48 statements in total covering both types of statement. Each type of statement has an equal number of true statements and false statements. It is assumed that visualisers respond more quickly to the appearance statements, because the objects can be readily represented as mental pictures and the information for the comparison can be obtained directly and rapidly from these images. In the case of the conceptual category items, it is assumed that verbalisers have a shorter response time because the semantic conceptual category membership is verbally abstract in nature and cannot be represented in visual form. The computer records the response time to each statement and calculates the Verbal-Visualiser Ratio. A low ratio corresponds to a verbaliser and a high ratio to a visualiser, with the intermediate position being described as biomodal.

This study followed Riding's recommendation for the measurements of Field Dependence/Independence and Verbaliser/Visualiser. In terms of Field Dependence/Independence, Riding's (1991) recommendations are that scores below 1.03 denote field-dependent individuals; scores of 1.36 and above denote field-independent individuals; students scoring between 1.03 and 1.35 are classed as Intermediate. Regarding the measurement of Verbaliser/Visualiser, the recommendations are scores below 0.98 denote verbalisers; scores of 1.09 and above denote visualisers; students scoring between 0.98 and 1.09 are classed as biomodal.

Procedure

The experiment consisted of several steps. Initially, the CSA was used to classify users' cognitive styles as Field Dependent /Intermediate/Field Independent (Experiment 1) or Verbaliser/Biomodal/Visualiser (Experiment 2). Subjects then viewed the 12 multimedia video clips. In order to counteract any order effects, the order in which clips were visualised was varied randomly for each participant. After the users had seen each clip once, the window was closed, and they had to answer a number of questions about the video clip they had just seen. The actual number of such questions depended on the video clip, and varied between 10 and 12. After the user had answered the set of questions pertaining to a particular video clip and the responses had been duly recorded, (s)he was asked to rate the enjoyment quality of the clip that had just been seen on a Likert scale of 1 - 6 (with scores of 1 and 6 representing the worst and, respectively, best perceived qualities possible). The user then went on and watched the next clip.

Users were instructed not to let personal bias towards the subject matter in the clip or production-related preferences (for instance, the way in which movie cuts had been made) influence their enjoyment quality rating of a clip. Instead, they were asked to judge a clip's enjoyment quality by the degree to which they, the users, felt that they would be satisfied with a general purpose multimedia service of such quality. Users were told that factors which should influence their quality rating of a clip included clarity and acceptability of audio signals, lip synchronisation during speech, and the general relationship between visual and auditory message components.

Data Analyses

In this study, the independent variables include the participants' cognitive styles, as well as clip categories and their degree of dynamism. The dependent variables were the two components of Quality of Perception: the level of understanding (QoP-IA, expressed as a percentage measure describing the proportion of questions that the user had correctly answered for each clip) as well as the level of enjoyment (QoP-LOE, expressed

on a six-point Likert scale). Data were analysed with the Statistical Package for the Social Sciences (SPSS) for Windows version (release 9.0). An ANalysis Of VAriance (ANOVA), suitable to test the significant differences of three or more categories, and t-test, suitable to identify the differences between two categories (Stephen & Hornby, 1997), were applied to analyse the participants' responses. A significance level of $p < 0.05$ was adopted for the study.

DISCUSSION OF RESULTS

Subject Content

Experiment 1

Our analysis has highlighted that the subject content (i.e., particular clip category) has a statistically significant impact on the QoP-IA level of participants (p=.0000). This confirms previous results (Ghinea & Thomas, 1998) and we extended our analysis to include the impact of users' cognitive styles. As depicted in Table 4, the clip on which participants performed best varied according to the users' cognitive style. Accordingly, intermediate and field-independent users had the highest level of understanding for the Snooker video clip. However, field- dependent users perform better in the Documentary clip. As Table 1 shows, the most discriminating feature between the two clips is the fact that the latter clip does not contain any textual description. The difference in the understanding corresponding to the different cognitive styles is thus probably due to the fact that field-dependent learners are "influenced by salient features" (Jonassen & Grabowski, 1993, p.88). Without the distraction of text description, field-dependent users could concentrate their learning on video clips, so they could have better performance. On the other hand, irrespective of the type of cognitive style, all users performed worst in the highly dynamic Rugby sports action clip, in which, as Table 4 shows, all media components were medium-strong purveyors of information. This finding seems to imply that users have difficulty concentrating on multiple, different sources of information, and that the dynamism of the clip is also a contributing factor to participants' level of understanding, as was confirmed by further analysis, presented in the section titled "Degree of Dynamism"..

The specific multimedia clip type also influences the QoP-LOE, namely the level of enjoyment experienced by users (p=.0000). As Table 5 shows, although the Documentary and Rugby video clips predominate in the "Most Enjoyed" and "Least Enjoyed" categories, only for field-dependent users does the choice of most/least enjoyed clip coincide with the clips on which the level of understanding is highest, respectively lowest (see Table 4, in this regard). These results are in line with those of Fullerton (2000) and Ford and Chen (2001), which showed that field- dependent users performed better in a learning environment matching their preferences; conversely, their performance will be reduced in a mismatched condition. Moreover, our results also show that the Forecast video clip was the one which field-

Table 4. Cognitive styles and QoP-IA in clip categories

	Field Dependent	Intermediate	Field Independent
Best Performance	Documentary	Snooker	
	63.84%	62.93%	63.46%
Worst Performance		Rugby	
	33.24%	37.5%	34.82%

Table 5. Cognitive styles and QoP-LOE of clip categories

	Field Dependent	Intermediate	Field Independent
Most Enjoyed	Documentary		Forecast
	3.18	2.86	3.02
Least Enjoyed	Rugby	Band	Rugby
	1.39	1.93	1.61

independent users enjoyed most. It is probable that the wealth of detail present in this clip (information was conveyed through all three channels, video, audio, and text) is what makes the clip appealing to this particular type of users, who concentrated primarily on procedural details when processing information in a learning context (Pask, 1976, 1979). This is in contrast to the "Most Enjoyed" clip (i.e. Documentary) for the other two categories of users, in which information was only conveyed through the video and audio streams.

Experiment 2

Our results indicate that clip categories, as given by their specific multimedia content matter, significantly influence participants' components of QoP-IA. This shows that the information assimilation scores are significantly influenced by the content being visualised; moreover, this observation is valid irrespective of the particular cognitive style of the participant. However, closer analysis reveals that different cognitive style groups have different favourite clips. Pop Music, which displays information using multiple channels, including video, audio, and text, is the favourite clip, from an information assimilation point of view, for biomodals who combine the characteristics of both verbalisers and visualisers and are particularly adept at receiving information from either textual descriptions or graphic presentations. However, we did obtain some significant results that contradict those of previous research (Laing, 2001; Riding & Watts, 1997)

Table 6. Favourite clips

	Verbaliser	Biomodal	Visualiser
Score	62.84%	62.98%	65.52%
	Documentary	Snooker	
Enjoyment	4.17	3.94	3.91
	Documentary	Pop Music	Documentary

Table 7. Least favourite clip

	Verbaliser	**Biomodal**	**Visualiser**
Score	35.59%	35.74%	34.49%
		Rugby	
Enjoyment	2.59	2.78	2.81
		Rugby	

(Tables 6 and 7). Although the Documentary clip does not display any text description, it is the clip in which, on average, verbalisers obtain the highest QoP-IA (F=10.592, df=5,40, p=.000). On the other hand, visualisers perform better in the Snooker clip, which, though static, includes information conveyed through video, audio, and text (F=14.8451, df=6,36, p=.000).

However, irrespective of cognitive style, we found that the Rugby clip was the one in which participants obtained the lowest QoP-IA scores (F=32.743, df=15,72, p=.000). Although this clip is similar in some respects to others studied by us (such as the Snooker clip, which also has an abundance of information being portrayed through video, audio, and textual means), its main distinguishing feature is its high dynamism; there is considerable temporal variability due to the high inter-frame differences specific to clips featuring action sports. We therefore assume that the reason why participants scored so lowly in terms of QoP-IA on this clip is precisely because of its high dynamism, a hypothesis that shall be further explored in the section titled "Degree of Dynamism".

Enjoyment will also influence users' performance, especially for verbalisers, who perform better and enjoy more the Documentary clip and performed worse and enjoyed less the Rugby clip. It is consistent with the results of previous research (Chen, 2002), which highlight that positive user perceptions of the learning environment can enhance their performance; conversely, negative attitudes will tend to hinder learning performance.

Degree of Dynamism

Multimedia clip dynamism was found to significantly impact upon participants' QoP-IA levels in our study (Figure 2). The correct one is that the level of significance was found to be p=.000 for field-dependent users and p=.001 for intermediate and field-independent users. Clip dynamism is given by Table 3, where the terms strong, medium, and weak were coded with the values of 3, 2, and 1, respectively. All users performed worst in the clips with strong dynamism. In particular, field- dependent users do not perform as well as field-independent and intermediate users. As suggested by previous works (Chen, 2002; Chen & Macredie, 2002), field-dependent users' performance was hindered in situations where they need to extract cues by themselves. Thus, in multimedia clips with strong dynamism that provided too many cues, field-dependent users might find it difficult to select relevant cues.

The dynamism of the visualised clips also influenced the level of enjoyment experienced by participants (p=.000). If a per-cognitive style analysis is pursued, we find that the level of enjoyment is influenced by the dynamism of the multimedia clip for both field-independent (p=.004) and field-dependent (p=.000) users. As

Figure 2. Impact of dynamism and cognitive styles on participants' QoP-IA

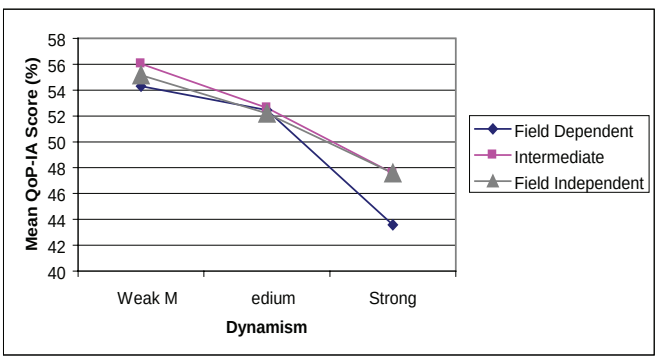

Figure 3. Impact of dynamism and cognitive styles on participants' QoP-LOE

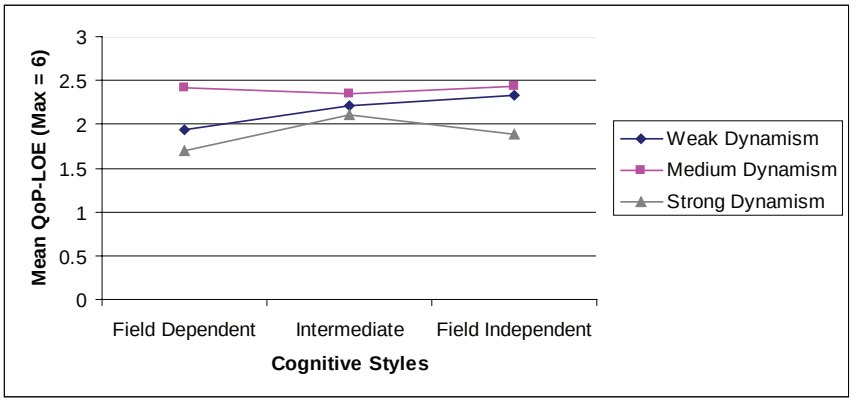
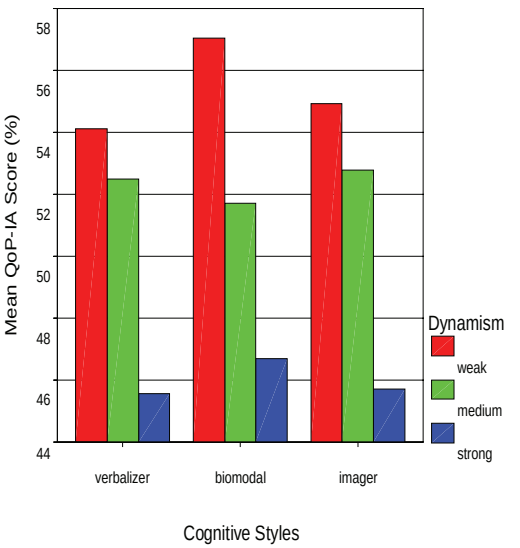


shown in Figure 3, both field-independent and field-dependent users experienced higher levels of enjoyment from the clips with medium dynamism, while strongly dynamic clips were liked least of all. However, dynamism does not seem to be a factor influencing multimedia clip enjoyment of intermediate users. One possible interpretation is that individuals possessing an Intermediate cognitive style employ a more versatile repertoire of information-seeking strategies. Versatile users, who have acquired the skill to move back and forth between different information-seeking strategies, are more capable of adapting themselves to suit the subject content presented by the multimedia video clips. This finding is consistent with the views of previous work, namely that a versatile strategy can be better equipped for multimedia learning technology (Chen & Ford, 1998; Paterson, 1996).

Analysis of the results obtained from the experiments shows that the degree of clip dynamism significantly impacts upon the QoP-IA component of QoP, irrespective of the user's cognitive style. The analysis has highlighted, moreover, the fact that the highest QoP-IA scores are obtained for clips which have a low degree of dynamism. Conversely, multimedia clips which have a high degree of dynamism have a negative impact on the user assimilation of the informational content being conveyed by the respective clips (Figure 4). Thus, clips which have relatively small inter-frame variability will facilitate higher QoP-IA scores: An object which might appear for only 0.5 seconds in a highly dynamic clip is less easily remembered than is the case when it appears for one second in a clip which is less dynamic.

As far as the QoP-LOE component is concerned, analysis of our results reveals that while

Figure 4. Cognitive styles and clip dynamism impact on QoP-IA



dynamism is a significant factor in the case of verbalisers and visualisers, this is not true of biomodals (Figure 5). As suggested by previous research (Riding & Rayner, 1998), biomodals can tailor learning strategies to the specific learning environments so the features of learning environments have no significant effects on their enjoyment. For verbalisers and visualisers, however, it was found that clips of medium dynamism had the highest levels of QoP-LOE, which suggests that such users do not find enjoyable clips which are static (or, conversely, highly dynamic). While the user may feel somewhat overwhelmed by a fast-paced clip, (s) he might possibly feel uninterested by a static clip with almost repetitive frame displays; it should come as no surprise, then, that such users prefer clips of medium dynamism, where they do not feel overwhelmed, but neither are they bored by the presentation of the subject matter concerned.

SUMMARY

This chapter has presented the results of two studies that looked at the impact of cognitive styles and multimedia content on users' subjective Quality of Perception. The latter is a term which encompasses not only a user's enjoyment, but also his/her level of understanding of visualised multimedia content. Each of the studies used a different dimension for categorising participants' cognitive style – thus, the first study used the Field Dependent/ Independent categorisation, whilst the second employed the Verbaliser/Visualiser dimension.

Our results reveal that multimedia video clip dynamism is an important factor impacting, irrespective of the particular dimension of cognitive style being employed, upon participants' QoP-IA levels. A similar conclusion as regards QoP-LOE can only be made, however, if the Field Dependent/Independent dimension is used. If one uses the Verbaliser/Visualiser dimension to classify cognitive style, clip dynamism has no significant effects on Biomodals, which, displaying characteristics of both Verbalisers and Visualisers, have adaptable preferences of accessing information and enjoy receiving information from multiple channels.

However, what our results do highlight, independent of the cognitive style taxonomy being used, is that multimedia content does have a significant influence on the user experience, as measured by the QoP metric. This would imply that in order to deliver an enhanced multimedia infotainment experience, multimedia content providers should focus on relatively static multimedia video and take into consideration the appropriateness of the subject matter in order to aid in the uptake and proliferation of distributed multimedia.

Chapter 7.8
Incorporating User Perception in Adaptive Video Streaming Systems

Nicola Cranley

Liam Murphy
University College Dublin, Ireland

ABSTRACT

There is an increasing demand for streaming video applications over both the fixed Internet and wireless IP networks. The fluctuating bandwidth and time-varying delays of best-effort networks makes providing good quality streaming a challenge. Many adaptive video delivery mechanisms have been proposed over recent years; however, most do not explicitly consider user-perceived quality when making adaptations, nor do they define what quality is. This chapter describes research that proposes that an optimal adaptation trajectory through the set of possible encodings exists, and indicates how to adapt transmission in response to changes in network conditions in order to maximize user-perceived quality.

INTRODUCTION

Best-effort IP networks are unreliable and unpredictable, particularly in a wireless environment. There can be many factors that affect the quality of a transmission, such as delay, jitter, and loss. Congested network conditions result in lost video packets, which, as a consequence, produce poor quality video. Further, there are strict delay constraints imposed by streamed multimedia traffic. If a video packet does not arrive before its playout time, the packet is effectively lost. Packet losses have a particularly devastating effect on the smooth continuous playout of a video sequence due to inter-frame dependencies. A slightly degraded quality but uncorrupted video stream is less irritating to the user than a randomly-corrupted stream. However, rapidly fluctuating quality should also be avoided as the

human vision system adapts to a specific quality after a few seconds, and it becomes annoying if the viewer has to adjust to a varying quality over short time scales (Ghinea, Thomas, & Fish, 1999). Controlled video quality adaptation is needed to reduce the negative effects of congestion on the stream while providing the highest possible level of service and quality. For example, consider a user watching some video clip; when the network is congested, the video server must reduce the transmitted bitrate to overcome the negative effects of congestion. In order to reduce the bitrate of the video stream, the quality of the video stream must be reduced by sacrificing some aspect of the video quality. There are a number of ways in which the quality can be adapted; for example, the image resolution (i.e. the amount of detail in the video image), the frame rate (i.e. the continuity of motion), or a combination of both can be adapted. The choice of which aspect of the video quality should depend on how the quality reduction will be perceived.

In the past few years, there has been much work on *video quality adaptation* and *video quality evaluation*. In general, video quality adaptation indicates how the bit rate of the video should be adjusted in response to changing network conditions. However, this is not addressed in terms of video quality, as for a given bit rate budget there are many ways in which the video quality can be adapted. Video quality evaluation measures the quality of video as perceived by the users, but current evaluation approaches are not designed for adaptive video streaming transmissions.

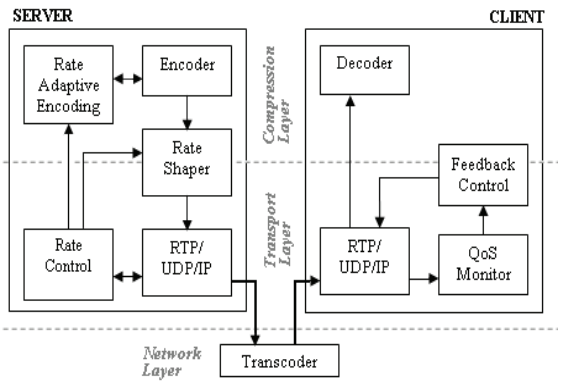
This chapter will firstly provide a generalized overview of adaptive multimedia systems and describe recent systems that use end-user perception as part of the adaptation process. Many of these adaptive systems rely on objective metrics to calculate the user-perceived quality. Several objective metrics of video quality have been developed, but they are limited and not satisfactory in quantifying human perception. Further, it can be argued that to date, objective metrics were not designed to assess the quality of an adapting video stream. As a case study, the discussion will focus on recent research that demonstrates how user-perceived quality can be used as part of the adaptation process for multimedia. In this work, the concept of an Optimal Adaptation Trajectory (OAT) has been proposed. The OAT indicates how to adapt multimedia in response to changes in network conditions to maximize user-perceived quality. Finally experimental subjective testing results are presented that demonstrate the dynamic nature of user-perception with adapting multimedia. The results illustrate that using a two-dimensional adaptation strategy based on the OAT out-performs one-dimensional adaptation schemes, giving better short-term and long-term user-perceived quality.

REVIEW OF ADAPTIVE MULTIMEDIA SYSTEMS

Given the seriousness of congestion on the smooth continuous play-out of multimedia, there is a strong need for adaptation. The primary goals of adapting multimedia are to ensure graceful quality adaptation, maintain a smooth continuous play-out and maximize the user-perceived quality. Multimedia servers should be able to intelligently adapt the video quality to match the available resources in the network. There are a number of key features that need to be considered in the development of an adaptive streaming system (Wang & Schulzrinne, 1999) such as feedback to relay the state of the network between client and server, the frequency of this feedback, the adaptation algorithm used, the sensitivity of the algorithm to feedback, and the resulting user-perceived quality.

However, the most important thing is how the system reacts, how it adapts to congestion, and the perceived quality that results from this adaptation.

Figure 1. Adaptation techniques



Adaptation Techniques

Broadly speaking, adaptation techniques attempt to reduce network congestion by matching the rate of the multimedia stream to the available network bandwidth. Without some sort of rate control, any data transmitted exceeding the available bandwidth would be discarded, lost, or corrupted in the network. Adaptation techniques can be classified into the following generalized categories: rate control, rate shaping, and rate adaptive encoding (Figure 1). Each of these techniques adapts the transmitted video stream to match the available resources in the network by either adapting the rate at which packets are sent or adjusting the quality of the delivered video (Wu, Hou, Zhu, Lee, Chiang, Zhang, & Chao, 2000, 2002). These are briefly described in the following sections.

Rate Control

Rate control is the most commonly-used mechanism employed in adaptive multimedia systems. Rate control can be implemented either at the server, the client, or a hybrid scheme whereby the client and server cooperate to achieve rate control.

- **Sender-based rate control:** On receipt of feedback from the client, the server adapts the transmission rate of the multimedia stream being transmitted in order to minimize the levels of packet loss at the client by matching the transmission rate of the multimedia stream to the available network bandwidth. Without any rate control, the data transmitted exceeding the available bandwidth would be discarded in the network.
- **Receiver-based rate control:** The clients control the receiving rate of video streams by adding/dropping layers. In layered multicast, the video sequence is compressed into multiple layers: a base layer and one or more enhancement layers. The base layer can be independently decoded and provides basic video quality; the enhancement layers can only be decoded together with the base layer, and they enhance the quality of the base layer.
- **Hybrid rate control:** This consists of rate control at both the sender and receiver. The hybrid rate control is targeted at multicast video and is applicable to both layered video and non-layered video. Typically, clients regulate the receiving rate of video streams by adding or dropping layers while the sender also adjusts the transmission rate of each layer based on feedback information from the receivers.

Unlike server-based schemes, the server uses multiple layers, and the rate of each layer may vary due to the hybrid approach of adapting both at the server and receiver.

Rate Shaping

Rate shaping is a technique to adapt the rate of compressed video bit-streams to meet some target bit rate by acting as a filter (or interface) between the compression layer and the transport layer. There are a number of filters that can be used to achieve rate shaping.

- **Frame-dropping filter:** This filter distinguishes between the different frame types in a video stream (i.e., I-, P- and B-frames). The frame-dropping filter is used to reduce the data rate of a video stream by discarding frames according to their relative importance. For example, B-frames are preferentially dropped, followed by P-frames and finally I-frames.
- **Frequency filter:** This filter performs filtering operations on the compression layer, for example, by discarding DCT coefficients at higher frequencies or reducing the color depth.
- **Re-quantization filter:** Re-quantizes the DCT coefficients. The filter extracts and de-quantizes the DCT coefficients from the compressed video stream then re-quantizes the coefficients with a larger quantization step which results in a reduced bitrate and reduced quality.

Rate Adaptive Encoding

Rate adaptive encoding performs adaptation by adjusting the encoding parameters which in turn adapts the output bit rate. However, adaptive encoding is constrained by the capabilities of the encoder and the compression scheme used. There are a number of encoding parameters that can be adapted in rate adaptive encoding, such as dynamically adapting the quantization parameter, frame rate, and/or the spatial resolution.

Discussion

The key questions that arise when developing or designing adaptation algorithms are how the system adapts and the perceived quality at the receiver.

There are a number of common components in each of the different adaptation techniques described. Many adaptation algorithms have a strong dependency on the choice of control parameters used within the adaptation process. For example, in a server-based rate control system, upon receipt of feedback the server either increases its transmission rate by α or decreases its rate by β. If the rate of α is chosen to be too large, the increased transmission rate could push the system into causing congestion, which can in turn cause the client to experience loss and poor perceived quality. However, if α is too small, the server will be very slow to make use of the extra available bandwidth and send a higher bit rate video stream. Thus, the algorithm is heavily dependent on the value of the control parameters, α and β, which drive the adaptation.

Even more problematic is translating rate into real video encoding parameters. Consider a simple system where the server is delivering video at 150kbps, and based on feedback, the algorithm indicates that the transmission rate should be increased to 160kps. The question that remains is: How should the extra 10kps be achieved, how can the video stream be adjusted to achieve this rate? This is further complicated by the limitations of the encoder to adapt the video. Layer-based schemes are equally problematic since there is no firm definition of what constitutes a base layer and each of the enhancement layers.

The most important issue that is often omitted in the design of adaptation algorithms is user-perception. User-perception should be incorporated into the adaptation algorithms, since it is the user who is the primary entity affected by adaptation, and should therefore be given priority in the adaptation decision-making process. For example, if a video clip is being streamed at a particular encoding configuration and the system needs to degrade the quality being delivered, how this adaptation occurs should be dictated by the users' perception. The way to degrade should be such as to have the least negative impact on the users' perception. There needs to be some sort of understanding of video quality and the perception of the video quality in order for adaptation to occur in an achievable and intelligent manner.

REVIEW OF OBJECTIVE METRICS

The main goal of objective metrics is to measure the perceived quality of a given image or video. Sophisticated objective metrics incorporate perceptual quality measures by considering the properties of the ***Human Visual System*** (HVS) in order to determine the visibility of distortions and thus the perceived quality. However, given that there are many factors that affect how users perceive quality, such as video content, viewing distance, display size, resolution, brightness, contrast, sharpness/fidelity, and colour, many objective metrics have limited success in calculating the perceived quality accurately for a diverse range of testing conditions and content characteristics. Several objective metrics of video quality have been proposed (Hekstra, 2002; van den Branden Lambrecht, 1996; Watson, Hu, & McGowan, 2000; Winkler, 1999), but they are limited and not satisfactory in quantifying human perception (Masry & Hemami, 2002; Yu & Wu, 2000).

In this section two key objective metrics, the ***Peak Signal to Noise Ratio*** (PSNR) and the ***Video Quality Metric*** (VQM) are reviewed. These two metrics have been widely applied to many applications and adaptation algorithms to assess video quality.

Peak Signal to Noise Ratio (PSNR)

The most commonly-used objective metric of video quality assessment is the ***Peak Signal to Noise Ratio*** (PSNR). The advantage of PSNR is that it is very easy to compute. However, PSNR does not match well to the characteristics of HVS. The main problem with using PSNR values as a quality assessment method is that even though two images are different, the visibility of this difference is not considered. The PSNR metric does not take the visual masking phenomenon or any aspects of the HVS into consideration, that is, every single errored pixel contributes to the decrease of the PSNR, even if this error is not perceived. For example, consider an image where the pixel values have been altered slightly over the entire image and an image where there is a concentrated distortion in a small part of the image both will result in the PSNR value however, one will be more perceptible to the user than the other. It is accepted that the PSNR does not match well to the characteristics of the HVS (Girod, 1993; van den Branden Lambrecht & Verscheure, 1996).

Video Quality Metric (VQM)

The ITU-T has recently accepted the Video Quality Metric (VQM) from the National Telecommunications and Information Administration (NTIA) as a recommended objective video quality metric that correlates adequately to human perception in ITU-T J.148 (2003) and ITU-T J.149 (2004). The ***Video Quality Metric*** (VQM) provides a means of objectively evaluating video quality. The system compares an original video clip and a processed video clip and reports a Video Quality Metric (VQM) that correlates to the perception of a typical end user. The VQM objective metrics are claimed to provide close approximations to the overall quality impressions, or mean opinion scores (Wolf & Pinson, 1999). The quality measurement process includes sampling of the original and processed video streams, calibration of the original and processed video streams, extraction of perception-based features, computation of video quality parameters, and finally calculation using various VQM models.

Using Objective Metrics for Multimedia Adaptation

Given the wide range of video quality metrics developed, the ***Video Quality Experts Group*** (VQEG) was formed in 1997 with the task of collecting reliable subjective ratings for a defined set of test sequences and to evaluate the performance of various objective video quality metrics (VQEG,

2005). In 2000, the VQEG performed a major study of various objective metrics on behalf of the ITU to compare the performances of various objective metrics against subjective testing in terms of prediction accuracy, prediction monotonicity, and prediction consistency. The results of the VQEG study found that no objective metric is able to fully replace subjective testing, but even more surprisingly, that no objective metric performed statistically better than the PSNR metric.

The main difficultly with video quality metrics is that even though they give an indication of the video quality, they do not indicate how the video quality should be adapted in an adaptive system. Furthermore, many of these objective metrics require a comparison between the reference clip and the degraded video clip in order to calculate the video quality. This comparison is often done on a frame-by-frame basis and therefore requires both the reference and degraded clips to have the same frame rate. The more sophisticated metrics proposed are extremely computationally intense and are unsuitable for use in a real-time adaptive system. Given the limitations of objective metrics, it has been recognized that user-perception needs to be incorporated in adaptation algorithms for streamed multimedia. There are emerging adaptive streaming systems being developed that address this issue (Muntean, Perry, & Murphy, 2004; Wang, Chang, & Loui, 2004).

OPTIMUM ADAPTATION TRAJECTORIES (OATS)

This section will focus on an approach that incorporates user-perception into adaptation algorithms for video streaming. This work proposes that there is an optimal way in which multimedia transmissions should be adapted in response to network conditions to maximize the user-perceived quality (Cranley, Murphy, & Perry, 2003). This is based on the hypothesis that within the set of different ways to achieve a target bit rate, there exists an encoding configuration that maximizes the user-perceived quality. If a particular multimedia file has *n* independent encoding configurations, then there exists an adaptation space with *n* dimensions. When adapting the transmission from some point within that space to meet a new target bit rate, the adaptive server should select the encoding configuration that maximizes the user-perceived quality for that given bit rate. When the transmission is adjusted across its full range, the locus of these selected encoding configurations should yield an ***Optimum Adaptation Trajectory*** (OAT) within that adaptation space.

This approach is applicable to any type of multimedia content. The work presented here focuses for concreteness on the adaptation of MPEG-4 video streams within a finite two-dimensional adaptation space defined by the range of the chosen encoding configurations. Each encoding configuration consists of a combination of frame rate and resolution and is denoted as [Frame rate $_{FPS}$, Resolution $_{R}$]. These encoding variables were chosen as they most closely map to the spatial and temporal complexities of the video content. The example shown in Figure 2(a) indicates that, when degrading the quality from an encoding configuration of 25fps and 100% resolution or [25_{FPS}, 100_{R}], there are a number of possibilities such as reducing the frame rate only, [X_{FPS}, 100_{R}], reducing the resolution only, [25_{FPS}, Y_{R}], or reducing a combination of both parameters, [U_{FPS}, V_{R}]. Each of these possibilities lies within a zone of ***Equal Average Bit Rate*** (EABR). The clips falling within a particular zone of EABR have different, but similar bit rates. For example, the bit rates corresponding to the encoding points [17_{FPS}, 100_{R}], [25_{FPS}, 79_{R}] and [25_{FPS}, 63_{R}] were 85, 88, and 82 kbps, respectively. To compare clips of exactly the same bit rate would require a target bit rate to be specified, and then the encoder would use proprietary means to achieve this bit rate by compromising the quality of the encoding in an unknown manner. Using zones of EABR effectively quantizes the bit rate of dif-

Figure 2(a). Adaptation possibilities

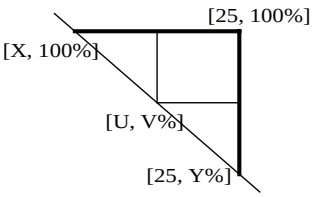


Figure 2(b). Adaptation space

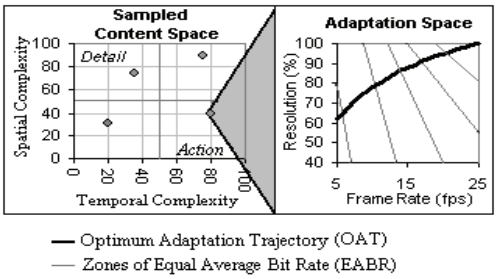


ferent video sequences with different encoding configurations. The boundaries of these zones of EABR are represented as linear contours for simplicity, since their actual shape is irrelevant for this scheme.

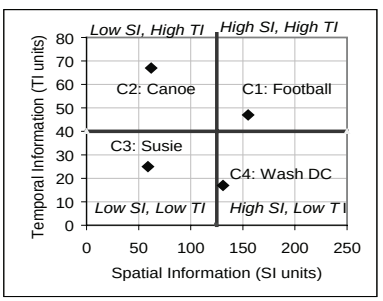
The OAT indicates how the quality should be adapted (upgraded or downgraded) so as to maximize the user-perceived quality. The OAT may be dependent on the characteristics of the content. There is a content space in which all types of video content exist in terms of ***spatial and temporal complexity*** (or *detail* and *action*). Every type of video content within this space can be expanded to an adaptation space as shown in Figure 2(b). Adaptation space consists of all possible dimensions of adaptation for the content. It can be implemented as part of an adaptive streaming server or adaptive encoder.

OAT Discovery

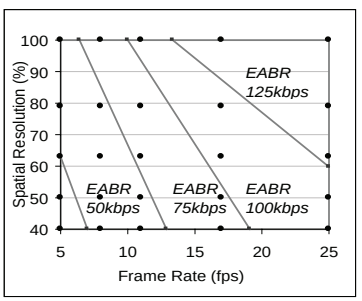
User perception of video quality may vary with the content type; for example, viewers may perceive action clips differently from slow-moving clips. Thus, there may exist a different OAT for different types of content based on their spatial and temporal characteristics. In order to characterize content in terms of its spatial and temporal complexity, a spatial-temporal grid was constructed, as shown in Figure 3(a). The spatial and temporal perceptual information of the content was determined using the metrics Spatial Information (SI) and Temporal Information (TI) (ITU-T P.910, 1999).

Eight different content types were selected based on their SI and TI values in order to cover as much of the Spatial-Temporal grid as possible. These test sequences were acquired from the VQEG. Each test sequence was then expanded to form an adaptation space, as shown in Figure

Figure 3(a). Spatial-temporal grid sampled with four content types for phase one of testing; (b) logarithmically-sampled adaptation space for content type C1

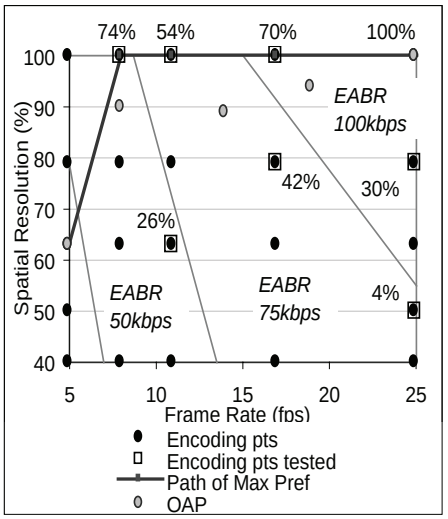


(a)



(b)

Figure 4. Subjective test results for content type, C3

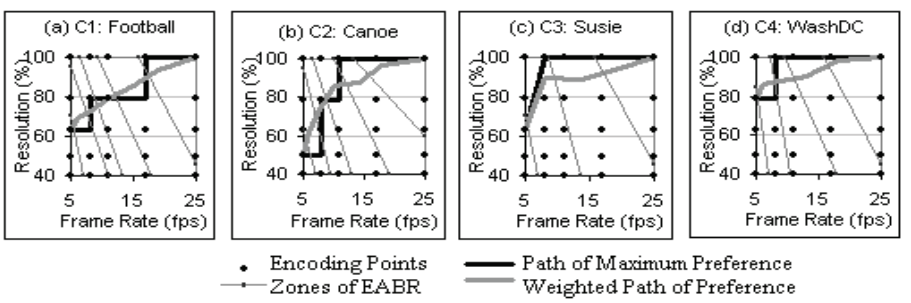


3(b). During the preparation of the test sequences for the subjective testing, the encoding method used was the "*most accurate*", that is, no target bit rate was specified, and the encoder followed the supplied encoding parameters as closely as possible regardless of the resulting bit rate.

The subjective testing consisted of two independent testers performing identical test procedures and using identical test sequences on subjects. Subjects were eliminated if the subject was either knowledgeable about video quality assessment or had any visual impairments. Testing was conducted in two phases. Phase One considered four test sequences, one taken from each quadrant of the SI-TI grid. To facilitate subjective testing and reduce the number of test cases, adaptation space was sampled using a logarithmic scale to reflect Weber's Law of Just Noticeable Difference (JND). Phase Two considered four different test sequences with similar SI-TI values to those used for Phase One. However, this time, the adaptation space was sampled using a linear scale. The main objective of having two different test phases was to verify and validate the results from Phase One. In addition, by using different encoding scales, it could be verified that the OAT was similar in shape regardless of whether a linear or logarithmic scale was used, and regardless of the encoding points tested.

There are a number of different subjective testing methodologies that are proposed by the ITU-T, including the ***Absolute Category Rating*** (ACR), the ***Degraded Category Rating*** (DCR), and ***Pair Comparison*** (PC) methods. The DCR method uses a five-point impairment scale whilst the ACR method uses a five-point quality grading scale, or alternatively a ***Continuous Quality Scale*** (CQS) (ITU-T P.910, 1999). However, by using such grading scales, it is criticized that different subjects may interpret the associated grading scale in different ways and use the grading scale in a non-uniform fashion (Watson, 1998). To overcome these difficulties in the grading procedure, the ***Forced Choice*** methodology is often employed. In the forced choice method, the subject is presented with a number of spatial or temporal alternatives in each trial. The subject is forced to choose the

Figure 5. Path of maximum user preference and weighted path of preference for four different content types



location or interval in which their preferred stimulus occurred. Using the forced choice method, the bias is binary, which simplifies the rating procedure and allows for reliability, verification, and validation of the results. The subjective tests consisted of a subject watching every combination of pairs of clips from each EABR zone for each content type and making a forced choice of the preferred encoding configuration. Intra-reliability and inter-reliability of a subject were factored into the test procedure by including repetition of the same test sequence presentation.

The diagram in Figure 4 shows the subjective test results obtained for a particular content type. The diagram consists of a grid of circular encoding points where the frame rate is on the x-axis and the resolution is on the y-axis. Through these encoding points are diagonal grey lines denoting the zones of EABR, ranging from 100kbps to 25kbps. The encoding points marked with a percentage preference value are those points that were tested within a zone of EABR. For example, in EABR-100kbps, there were two encoding configurations tested, [17_{FPS}, 100_{R}] and [25_{FPS}, 79_{R}]. Seventy percent of the subjects preferred encoding configuration [17_{FPS}, 100_{R}], while the remaining 30% preferred encoding configuration [25_{FPS}, 79_{R}]. However, in the left-most zone of EABR, the preferred encoding configuration is [5_{FPS}, 63_{R}]. In this zone of EABR there are three encoding configurations, but since the frame rate is the same, the preferred encoding configuration is that with the highest resolution, [5_{FPS}, 63_{R}].

The ***Path of Maximum Preference*** is the path through the zones of EABR joining the encoding configurations with the maximum user preference. Weighted points were then used to obtain the ***Optimal Adaptation Perception (OAP)*** points. The weighted points were interpolated as the sum of the product of preference with encoding configuration. For example, 70% of subjects preferred encoding [17_{FPS}, 100_{R}] and 30% preferred encoding point [25_{FPS}, 79_{R}]. The weighted vector of these two encoding configurations is [$70\%(17_{FPS})+30\%(25_{FPS})$, $70\%(100_{R})+30\%(79_{R})$] which equals OAP point [19.4_{FPS}, 93.7_{R}]. The ***Weighted Path of Preference*** is the path joining the OAPs. There are two possible paths which can be used to represent the OAT: the path of maximum user preference, and the weighted path of preference. It seems likely that by using the weighted path of preference, the system can satisfy more users by providing a smooth graceful quality adaptation trajectory. Using the same subjective testing methodology, the OAPs in each zone of EABR were compared against the maximum preferred encoding and all other encoding configurations. In all cases, the interpolated OAP did not have a statistically-significant preference from the maximum preferred encoding indicating that this simple weighted vector approach is acceptable. It was also observed that there was a higher incidence of forced choices when the maximum preferred encoding and the OAP were close together.

Figure 5 shows the paths of maximum preference and weighted paths of preference for the four content types used during Phase One of testing. It can be clearly seen from the paths of maximum user preference that when there is high action (C1 and C2), the resolution is less dominant regardless of whether the clip has high spatial characteristics or not. This implies that the user is more sensitive to continuous motion when there is high temporal information in the video content. Intuitively this makes sense as when there is high action in a scene; often the scene changes are too fast for the user to be able to assimilate the scene detail. Conversely, when the scene has low temporal requirements (C3 and C4), the resolution becomes more dominant regardless of the spatial characteristics.

Objective metrics were investigated to determine whether they yielded an OAT that correlated to that discovered using subjective testing. The results showed that there is a significant difference between the adaptation trajectories yielded using objective metrics and subjective testing techniques. This suggests that *measuring quality*

and *adapting quality based on this measurement* are different tasks.

OATS IN PRACTICE

In this section, how user-perception is affected by adapting video quality is investigated. In particular, the user-perceived quality is compared when video quality is varied by adapting the frame rate only, the resolution only, or adapting both the frame rate and the resolution using the OAT. Streaming multimedia over best-effort networks is becoming an increasingly important source of revenue. A content provider is unlikely to have the resources to provide real-time adaptive encoding for each unicast request and, as such, reserves this for "live" multicast sessions only. Typically, pre-encoded content is transmitted by unicast streams where the client chooses the connection that most closely matches their requirements. For such unicast sessions, the adaptive streaming server can employ several techniques to adapt the pre-encoded content to match the clients' resources. In such adaptive streaming systems, two techniques that are most commonly used are frame dropping and stream switching. The OAT shows how to stream the video in order to maximize the user's perceived quality in a two-dimensional adaptation space defined by frame rate and resolution (Figure 6). Adaptive frame rate can be achieved by frame dropping, while adapting spatial resolution can be achieved using track or stream switching.

All adaptation algorithms behave in an A-Increase/B-Decrease manner where A and B are the methods of change and can be either Additive, Multiplicative, Proportional, Incremental, or Decremented (Figure 7). When there is no congestion, the server increases its transmission rate either additively (AI), proportionally (PI), or multiplicatively (MI), and similarly when there is congestion, it decreases its transmission rate either additively (AD), proportionally (PD), or

Figure 6. One-dimensional versus two-dimensional adaptation

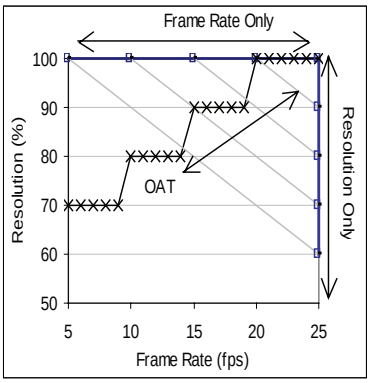


Figure 7. AIMD and MIMD

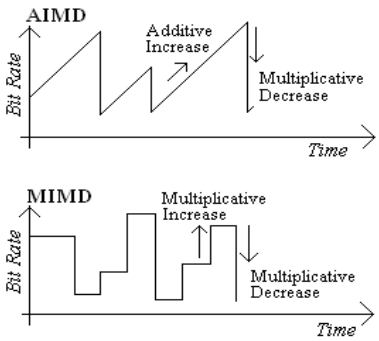


multiplicatively (MD). There are many ways to adapt video quality, for example:

- **Additive Increase/Multiplicative Decrease** (AIMD) (Chiu & Jain, 1989)
- **Additive Increase/Additive Decrease** (AIAD),
- **Additive Increase/Proportional Decrease** (AIPD) (Venkitaraman, Kim, Lee, Lu, & Bharghavan, 1999),
- **Multiplicative Increase/Multiplicative Decrease** (MIMD) (Turletti & Huitema, 1996).

In general, all rate-control algorithms exhibit some form of AI and AD behavior, although the

majority of adaptation algorithms are AIMD (Feamster, Bansal, & Balakrishnan, 2001). Thus the perception of adapting video quality is assessed in three different test cases. The first test assesses user perception when quality is adapted up in an AI manner, while the second assesses perception when quality is degraded down in an AD manner. Finally, the third assesses quality adapting in an Additive Increase/Multiplicative Decrease (AIMD) manner.

Test Methodology

The Forced Choice methodology is suitable for clips lasting not longer than 15 seconds. For video clips lasting longer than this duration, there are ***recency*** and ***forgiveness*** effects by the subject, which are a big factor when the subject must grade the overall quality of a video sequence. For example, the subject may forget and/or forgive random appearances of content-dependent artifacts when they are making their overall grade of the video sequence. To test clips of a longer duration, a different test methodology to the forced choice method needs to be applied to overcome the forgiveness and recency effects and to ensure the subject can make an accurate judgement.

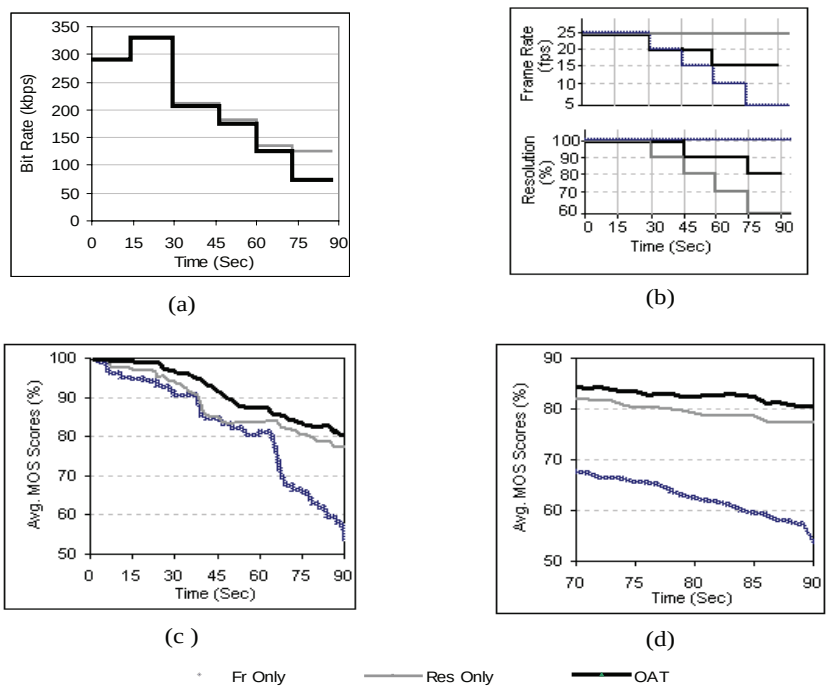
The ***Single Stimulus Continuous Quality Evaluation*** (SSCQE) methodology is intended for the presentation of sequences lasting several minutes (ITU-R BT.500-7, 1997). Continuous evaluation is performed using a slider scale on the screen to record the subjects' responses without introducing too much interference or distraction, and provides a trace of the overall quality of the sequence (Pinson & Wolf, 2003). A reference clip was played out at the beginning of the test so that the subjects were aware of the highest quality sequence. The three varying quality sequences were then presented in random order to each subject in turn. As each sequence was played out, the subject continuously rated the quality of the sequence using the slider. When the slider is moved, the quality grade of the slider is captured and related to the playout time of the media. The ***Mean Opinion Score*** (MOS) and standard deviation are calculated at each media time instant. In this case, each media time instant corresponds to one second of media. The MOS and standard deviation is calculated for each clip segment.

The test sequence chosen for this experiment contains a wide range of spatial and temporal complexity. The test sequence contains periods of high temporal complexity that are generally bursty containing many scene changes. In this test sequence, periods of high temporal complexity are generally followed by periods of relatively low temporal complexity but high spatial complexity consisting of detailed scenes such as facial close-ups and panoramic views. This test sequence contains a broad diversity of complexity and is typical of film trailers. The test sequence was divided into segments of 15 seconds duration, and each segment was encoded at various combinations of spatial resolution and frame rate. These video segments were then pieced together seamlessly to produce three varying bit rate versions of the test sequence. It was necessary to control and align each adaptation in each of the test sequences used. During these tests, it is assumed that some mechanism is implemented that informs the streaming server of the required transmission bit rate.

Results

Three scenarios were tested: First, the quality is adapted down from the best to worst; second, the quality is upgraded from worst to best; and third, the quality varies in an additive increase/multiplicative decrease fashion. The first two tests are complementary and are designed to assess symmetrical perception, that is, whether subjects perceive quality increases and quality decreases uniformly. The third test is designed to test quality perception in a typical adaptive network environment. Of particular interest are the MOS scores when the quality is decreased.

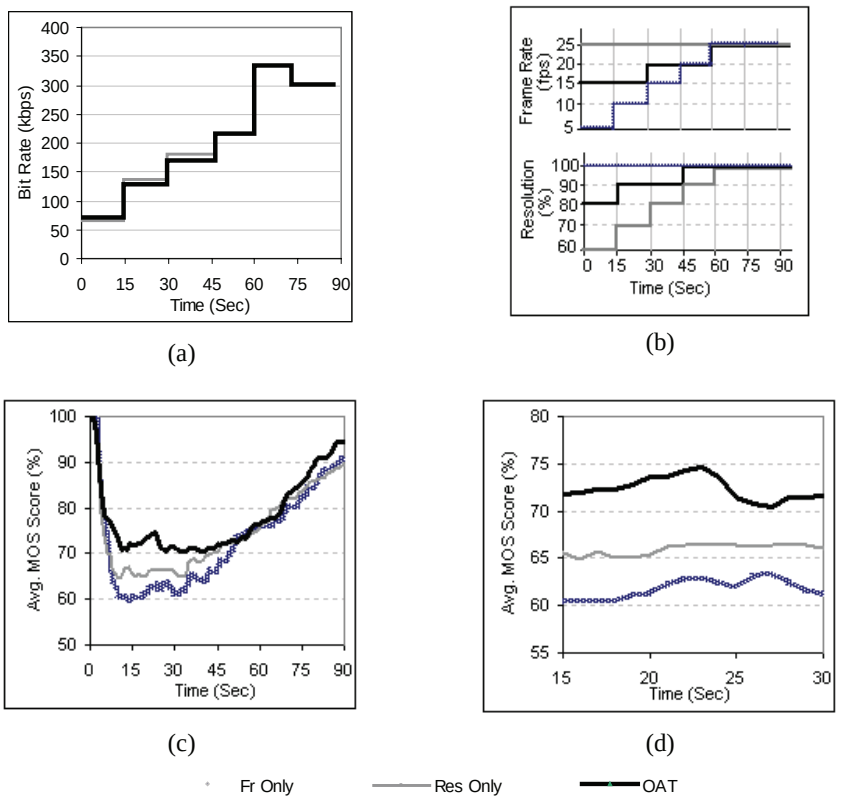
Figure 8. Time series during additive decrease (AD) in quality; (a) Segment average bit rate variations over time; (b) Video encoding parameter variations over time; (c) MOS Scores over time; (d) MOS Scores during period of lowest quality



Additive Decrease Quality Adaptation

In this test, the quality of the clip degrades from the best quality to the worst quality. Figure 8(a) shows the bit rate decreasing as the quality degrades. Figure 8(b) shows the encoding configuration of frame rate and resolution for each segment as the quality is adapting down in either the frame rate dimension only, or the resolution dimension only, or using the OAT adapting down in both the frame rate and resolution dimensions. Through time interval 0-45 seconds, the resolution and frame rate dimensions are perceived the same (Figure 8(c). In time interval 45-60 seconds, there appears to be an imperceptible difference between a decrease in resolution from 80_R to 70_R. Using the OAT, there is a smooth decrease in the MOS scores, which outperforms both one-dimensional adaptation of frame rate and resolution. During time interval 45-60 seconds, there is high action in the content which may explain the sharp decrease in the MOS scores for adapting the frame rate only. When there is high action, subjects prefer smooth continuous motion. Further, when there is high action content, reductions in spatial resolution cannot be perceived as clearly as there is too much happening in the video clip for the detail to be perceived properly. Figure 8(d) shows a close up view of MOS scores during the lowest quality level in time interval 70-90 seconds, the frame rate is perceived worst of all while the resolution performs very well. This may be due to the fact that the bit rate for the resolution is significantly greater than the two other methods. It was undesirable to achieve a lower bit rate for the resolution at 60%, as this would require a target bit rate to be set in the encoder.

Figure 9. Time series during additive increase (AI) in quality; (a) Segment average bit rate variations over time; (b) Video encoding parameter variations over time; (c) MOS Scores over time; (d) MOS Scores during period of lowest quality



Additive Increase Quality Adaptation

In this test, the quality of the clip upgrades from the worst quality to the best quality. Figure 9(b) shows the encoding configuration of frame rate and resolution as the quality is adapting up in either the frame rate dimension only or the resolution dimension only or using the OAT adapting down in both the frame rate and resolution dimensions. During this experiment, the slider is placed at the highest quality value on the rating scale when the clip begins. It can be seen that it took subjects several seconds to react to the quality level and adjust the slider to the appropriate value (Figure 9(c)). At low quality, subjects perceive adaptation using the OAT better than one-dimensional adaptation. The quality is slowly increasing, however subjects do not seem to notice the quality increasing nor do they perceive it significantly differently – indicating that subjects are more aware of quality when it is low (Figure 9(d)).

AIMD Adaptation

This section presents the results for AIMD adaptation, as might be expected from a TCP-friendly rate control mechanism. The same bit rate variation patterns were obtained in these three sequences by adapting quality in the frame rate dimension only, the spatial resolution dimension only, or both frame rate and spatial resolution dimensions, as shown in Figure 10(a). The traces in Figures 10(b) show the encoding configuration of frame

rate or resolution for each segment as the quality was adapted in either the frame rate dimension only, or the resolution dimension only, or using the OAT adapting in both the frame rate and resolution dimensions.

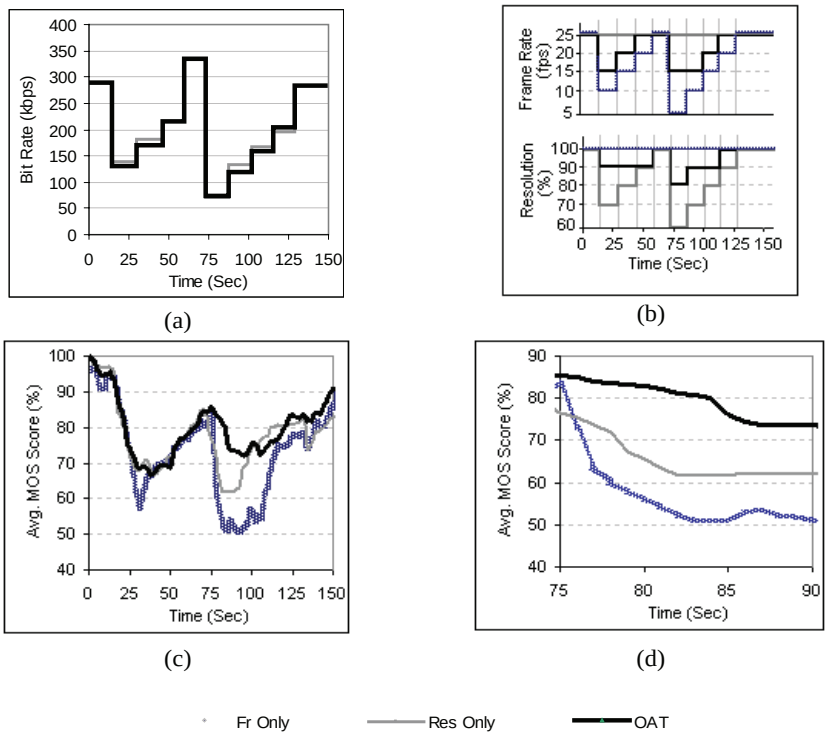
In Figure 10(a), it can be seen that although the first bit-rate reduction occurs at time 15 seconds, it is not fully perceived until time 28 seconds because there is a time delay for subjects to react to the quality adaptation. At time interval 70-90 seconds, a larger drop in bit rate occurs resulting in the lowest quality level that might reflect a mobile user entering a building. The MOS scores for adapting only the frame rate and spatial resolution are quick to reflect this drop. However, using the OAT, it takes subjects much longer to perceive this drop in quality. This is a high action part of the sequence and so the reduced frame rate is perceived more severely. The standard deviation of MOS scores using the OAT was much less than that for adapting frame rate only or spatial resolution only.

Discussion

From the experiments reported here, it appears that if a user's average bit rate changes from being quite near their maximum to near the minimum that they can tolerate, then a one-dimensional adaptation policy will cause the perceived quality to degrade quite severely. Using the two-dimensional adaptation strategy given by the OAT allows the bit rate to be dropped quite dramatically but maintain substantially better user-perceived quality.

In addition to the greater bit rate adaptation range achieved using the OAT, adaptation using the two-dimensional OAT out-performs one-dimensional adaptation using frame rate or spatial

Figure 10. Time series during additive increase multiplicative decrease (AIMD) in quality; (a) Segment average bit rate variations over time; (b) Video encoding parameter variations over time; (c) MOS Scores over time; (d) MOS Scores during period of lowest quality



resolution and reduces the variance of perception. From the various experiments conducted, subjects perceived adapting frame rate the worst, then resolution, and the OAT best of all. It was observed that there is a time delay of several seconds for subjects to react to quality adaptations. It was also observed that quality perception is asymmetrical when adapting the quality down and adapting quality up: Users are more critical of degradations in quality and less rewarding of increased quality. Similar observations were reported in Pinson and Wolf (2003).

Perception is strongly dependent on the spatio-temporal characteristics of the content. Given this understanding of user-perception, adaptation algorithms should consider the contents characteristics when making adaptation decisions. Also, frequent quality adaptation should be avoided to allow the users to become familiar with the video quality. In the experiments, the globally-averaged OAT was used, but the OAT can be dynamic if the contents' spatial and temporal characteristics are known at a given instant, thus making it more flexible to adapt according to the contents' characteristics and maximize user-perceived quality. It is expected that a dynamic OAT that adapted on the changing complexity of the content would yield even higher MOS scores.

SUMMARY

This chapter provided a brief overview of adaptive streaming systems and identified key limitations of the techniques currently in use. Quite often, adaptation algorithms omit the user-perceived quality when making adaptation decisions. Recent work in multimedia adaptation has addressed this problem by incorporating objective video quality metrics into the adaptation algorithm, thereby making the adaptation process quality-aware. However, these objective metrics have limited efficacy in assessing the user-perceived quality. As a case study, we have focused on describing recent research that attempts to address both the limitations of objective video quality metrics and adaptation techniques.

This work proposed that there is an Optimal Adaptation Trajectory (OAT), which basically states that there is an optimal way video should be adapted that maximizes the user-perceived quality. More specifically, within the set of different ways to achieve a target bit rate given by an adaptation algorithm, there exists an encoding that maximizes the user-perceived quality. Furthermore, the OAT is dependent on the spatio-temporal characteristics of the content. We have described a subjective methodology to discover the OATs through subjective testing, and applied it to finding OATs for various MPEG-4 video clips. Further it was shown that using a two-dimensional adaptation strategy given by the OAT allows the bit rate to be dropped quite dramatically but maintain substantially better user-perceived quality over one-dimensional adaptation strategies. In addition to the greater bit rate adaptation range achieved using the OAT, adaptation using the two-dimensional OAT out-performs one-dimensional adaptation using frame rate or spatial resolution and reduces the variance of perception.

Future work will assess the possibility of using and/or modifying existing objective metrics in order to mimic the OATs found by subjective methods and enable the development of a dynamic OAT. This will involve a greater analysis of the relationship between content characteristics and the corresponding OAT to determine the sensitivity of an OAT to the particular video being transmitted.

ABSTRACT

Recent advances in technology have made it possible to easily amass large collections of digital media. These media offer new opportunities and place great demands for new digital content user-interface and management systems which can help people construct, organize, navigate, and share digital collections in an interactive, face-to-face social setting. In this chapter, we have developed a user-centric algorithm for visualization and layout for content-based image retrieval (CBIR) in large photo libraries. Optimized layouts reflect mutual similarities as displayed on a two-dimensional (2D) screen, hence providing a perceptually intuitive visualization as compared to traditional sequential one-dimensional (1D) content-based image retrieval systems. A framework for user modeling also allows our system to learn and adapt to a user's preferences. The resulting retrieval, browsing and visualization can adapt to the user's (time-varying) notions of content, context and preferences in style and interactive navigation.

INTRODUCTION

Personal Digital Historian (PDH) Project

Recent advances in digital media technology offer opportunities for new story-sharing experiences beyond the conventional digital photo album (Balabanovic et al., 2000; Dietz & Leigh, 2001). The Personal Digital Historian (PDH) project is an ongoing effort to help people construct, organize, navigate and share digital collections in an interactive multiperson conversational setting (Shen et al., 2001; Shen et al., 2003). The research in PDH is guided by the following principles:

1. The display device should enable natural face-to-face conversation: not forcing everyone to face in the same direction (desktop) or at their own separate displays (hand-held devices).
2. The physical sharing device must be convenient and customary to use: helping to make the computer disappear.
3. Easy and fun to use across generations of users: minimizing time spent typing or formulating queries.
4. Enabling interactive and exploratory storytelling: blending authoring and presentation.

Current software and hardware do not meet our requirements. Most existing software in this area provides users with either powerful query methods or authoring tools. In the former case, the users can repeatedly query their collections of digital content to retrieve information to show someone (Kang & Shneiderman, 2000). In the latter case, a user experienced in the use of the authoring tool can carefully craft a story out of his or her digital content to show or send to someone at a later time. Furthermore, current hardware is also lacking. Desktop computers are not suitably designed for group, face-to-face conversation in a social setting, and handheld story-telling devices have limited screen sizes and can be used only by a small number of people at once. The objective of the PDH project is to take a step beyond.

The goal of PDH is to provide a new digital content user-interface and management system enabling face-to-face casual exploration and visualization of digital contents. Unlike conventional desktop user interface, PDH is intended for multiuser collaborative applications on single display groupware. PDH enables casual and exploratory retrieval, and interaction with and visualization of digital contents.

We design our system to work on a touch-sensitive, circular tabletop display (Vernier et al., 2002), as shown in Figure 1. The physical PDH table that we use is a standard tabletop with a top projection (either ceiling mounted or tripod mounted) that displays on a standard whiteboard as shown in the right image of Figure 1. We use two Mimio (www.mimio.com/meet/mimiomouse) styluses as the input devices for the first set of user experiments. The layout of the entire tabletop display consists of (1) a large story-space area encompassing most of the tabletop until the perimeter, and (2) one or more narrow arched control panels (Shen et al., 2001). Currently, the present PDH table is implemented using our DiamondSpin (www.merl.com/projects/diamondspin) circular table Java toolkit. DiamondSpin is intended for multiuser collaborative applications (Shen et al., 2001; Shen et al., 2003; Vernier et al., 2002).

The conceptual model of PDH is to focus on developing content organization and retrieval metaphors that can be easily comprehended by users without distracting from the conversation. We adopt a model of organizing the materials using the four questions essential to storytelling: who, when, where, and what (the four Ws). We do not currently support why, which is also useful for storytelling. Control panels located on the perimeter of the table contain buttons labeled "people," "calendar," "location," and "events," corresponding to these four questions. When a

user presses the "location" button, for example, the display on the table changes to show a map of the world. Every picture in the database that is annotated with a location will appear as a tiny thumbnail at its location. The user can pan and zoom in on the map to a region of interest, which increases the size of the thumbnails. Similarly, by pressing one of the other three buttons, the user can cause the pictures to be organized by the time they were taken along a linear timeline, the people they contain, or the event keywords with which the pictures were annotated. We assume the pictures are partially annotated. Figure 2 shows an example of navigation of a personal photo album by the four-Ws model. Adopting this model allows users to think of their documents in terms of how they would like to record them as part of their history collection, not necessarily in a specific hierarchical structure. The user can make selections among the four Ws and PDH will automatically combine them to form rich Boolean queries implicitly for the user (Shen et al., 2001; Shen, Lesh, Vernier, Forlines, & Frost, 2002; Shen et al., 2003; Vernier et al., 2002).

The PDH project combines and extends research in largely two areas: (i) human-computer interaction (HCI) and interface (the design of the shared-display devices, user interface for storytelling and online authoring, and storylistening) (Shen et al., 2001, 2002, 2003; Vernier et al., 2002); (ii) content-based information visualization, presentation and retrieval (user-guided image layout, data mining and summarization) (Moghaddam et al., 2001, 2002, 2004; Tian et al., 2001, 2002). Our work has been done along these two lines. The work by Shen et al. (2001, 2002, 2003) and Vernier et al. (2002) focused on the HCI and interface design issue of the first research area. The work in this chapter is under the context of PDH but focuses on the visualization, smart layout, user modeling and retrieval part. In this chapter, we propose a novel visualization and layout algorithm that can enhance informal storytelling using personal digital data such as photos, audio and video in a face-to-face social setting. A framework for user modeling also allows our system to learn and adapt to a user's preferences. The resulting retrieval, browsing and visualization can adapt to the user's (time-varying) notions of content, context and preferences in style and interactive navigation.

Related Work

In content-based image retrieval (CBIR), most current techniques are restricted to matching image appearance using primitive features such as color, texture, and shape. Most users wish to retrieve images by semantic content (the objects/events depicted) rather than by appearance. The resultant *semantic gap* between user expectations and the current technology is the prime cause of the poor takeup of CBIR technology. Due to the semantic gap (Smeulders et al., 2000), visualization becomes very important for user to navigate the complex query space. New visualization tools are required to allow for user-dependent and goal-dependent choices about what to display and how to provide feedback. The query result has an inherent display dimension that is often ignored. Most methods display images in a 1D list in order of decreasing similarity to the query images. Enhancing the visualization of the query results is, however, a valuable tool in helping the user navigate query space. Recently, Horoike and Musha (2000), Nakazato and Huang (2001), Santini and Jain (2000), Santini et al. (2001), and Rubner (1999) have also explored toward content-based visualization. A common observation in these works is that the images are displayed in 2D or 3D space from the projection of the high-dimensional feature spaces. Images are placed in such a way that distances between images in 2D or 3D reflect their distances in the high-dimensional feature space. In the works of Horoike and Musha (2000) and Nakazato and Huang (2001), the users can view large sets of images in 2D or 3D space and user navigation is allowed. In the

Figure 1. PDH table (a) an artistic rendering of the PDH table (designed by Ryan Bardsley, Tixel HCI www.tixel.net) and (b) the physical PDH table

(a)

(b)

works of Nakazato and Huang (2001), Santini et al. (2000, 2001), the system allows user interaction on image location and forming new groups. In the work of Santini et al. (2000, 2001), users can manipulate the projected distances between images and learn from such a display.

Our work (e.g., Tian et al., 2001, 2002; Moghaddam et al., 2001, 2002, 2004) under the context of PDH shares many common features with the related work (Horoike & Musha, 2000; Nakazato & Huang, 2001; Santini et al., 2000, 2001; Rubner, 1999). However, a learning mechanism from the display is not implemented in Horoike and Musha (2000), and 3D MARS (Nakazato & Huang, 2001) is an extension to our work (Tian et al., 2001; Moghaddam et al. 2001) from 2D to 3D space. Our system differs from the work of Rubner (1999) in that we adopted different mapping methods. Our work shares some features with the work by Santini and Jain (2000) and Santini et al. (2001) except that our PDH system is currently being incorporated into a much broader system for computer human-guided navigating, browsing, archiving, and interactive storytelling with large

Figure 2. An example of navigation by the four-Ws model (Who, When, Where, What)

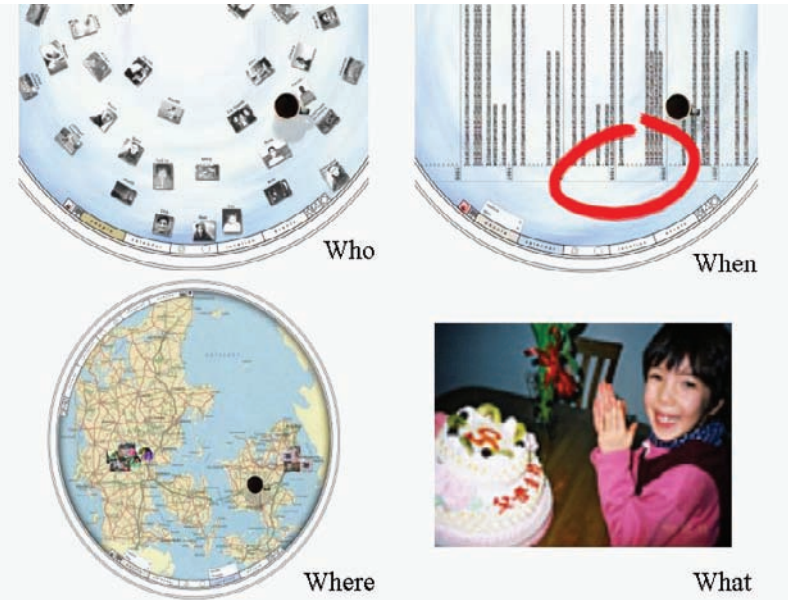

photo libraries. The part of this system described in the remainder of this chapter is, however, specifically geared towards adaptive user modeling and relevance estimation and based primarily on visual features as opposed to semantic annotation as in Santini and Jain (2000) and Santini et al. (2001).

The rest of the chapter is organized as follows. In Content-Based Visualization, we present designs for uncluttered visualization and layout of images (or iconic data in general) in a 2D display space for content-based image retrieval (Tian et al., 2001; Moghaddam et al., 2001). In Context and User Modeling, we further provide a mathematical framework for user modeling, which adapts and mimics the user's (possibly changing) preferences and style for interaction, visualization and navigation (Moghaddam et al., 2002, 2004; Tian et al., 2002). Monte Carlo simulations in the Statistical Analysis section plus the next section on User Preference Study have demonstrated the ability of our framework to model or "mimic" users, by automatically generating layouts according to user's preference. Finally, Discussion and Future Work are given in the final section.

CONTENT-BASED VISUALIZATION

With the advances in technology to capture, generate, transmit and store large amounts of digital imagery and video, research in content-based image retrieval (CBIR) has gained increasing attention. In CBIR, images are indexed by their visual contents such as color, texture, and so forth. Many research efforts have addressed how to extract these low-level features (Stricker & Orengo, 1995; Smith & Chang, 1994; Zhou et al., 1999), evaluate distance metrics (Santini & Jain, 1999; Popescu & Gader, 1998) for similarity measures and look for efficient searching schemes (Squire et al. 1999; Swets & Weng, 1999).

In this section, we present a user-centric algorithm for visualization and layout for content-based image retrieval. Image features (visual and/or semantic) are used to display retrievals as

thumbnails in a 2D spatial layout or "configuration" which conveys pair-wise mutual similarities. A graphical optimization technique is used to provide maximally uncluttered and informative layouts. We should note that one physical instantiation of the PDH table is that of a roundtable, for which we have in fact experimented with polar coordinate conformal mappings for converting traditional rectangular display screens. However, in the remainder of this chapter, for purposes of ease of illustration and clarity, all layouts and visualizations are shown on rectangular displays only.

Traditional Interfaces

The purpose of automatic content-based visualization is augmenting the user's understanding of large information spaces that cannot be perceived by traditional sequential display (e.g., by rank order of visual similarities). The standard and commercially prevalent image management and browsing tools currently available primarily use tiled sequential displays — *that is,* essentially a simple 1D similarity based visualization.

However, the user quite often can benefit by having a global view of a working subset of retrieved images in a way that reflects the relations between *all pairs* of images — that is, N^2 measurements as opposed to only N. Moreover, even a narrow view of one's immediate surroundings defines "context" and can offer an indication on how to explore the dataset. The wider this "visible" horizon, the more efficient the new query will be formed. Rubner (1999) proposed a 2D display technique based on multidimensional scaling (MDS) (Torgeson, 1998). A global 2D view of the images is achieved that reflects the mutual similarities among the retrieved images. MDS is a nonlinear transformation that minimizes the stress between high-dimensional feature space and low-dimensional display space. However, MDS is rotation invariant, nonrepeatable (nonunique), and often slow to implement. Most critically, MDS (as well as some of the other leading nonlinear dimensionality reduction methods) provide high-to-low-dimensional projection operators that are not analytic or functional in form, but are rather defined on a point-by-point basis for each given dataset. This makes it very difficult to project a new dataset in a functionally consistent way (without having to build a post-hoc projection or interpolation function for the forward mapping each time). We feel that these drawbacks make MDS (and other nonlinear methods) an unattractive option for real-time browsing and visualization of high-dimensional data such as images.

Improved Layout and Visualization

We propose an alternative 2D display scheme based on Principal Component Analysis (PCA) (Jolliffe, 1996). Moreover, a novel window display optimization technique is proposed which provides a more perceptually intuitive, visually uncluttered and informative visualization of the retrieved images.

Traditional image retrieval systems display the returned images as a list, sorted by decreasing similarity to the query. The traditional display has one major drawback. The images are ranked by similarity to the query, and relevant images (as for example used in a relevance feedback scenario) can appear at separate and distant locations in the list. We propose an alternative technique to MDS (Torgeson, 1998) that displays mutual similarities on a 2D screen based on visual features extracted from images. The retrieved images are displayed not only in ranked order of similarity from the query but also according to their mutual similarities, so that similar images are grouped together rather than being scattered along the entire returned 1D list.

Visual Features

We will first describe the low-level visual feature extraction used in our system. There are three

visual features used in our system: color moments (Stricker & Orengo, 1995), wavelet-based texture (Smith & Chang, 1994), and water-filling edge-based structure feature (Zhou et al., 1999).

The color space we use is HSV because of its decorrelated coordinates and its perceptual uniformity (Stricker & Orengo, 1995). We extract the first three moments (mean, standard deviation and skewness) from the three-color channels and therefore have a color feature vector of length $3\times3 = 9$.

For wavelet-based texture, the original image is fed into a wavelet filter bank and is decomposed into 10 decorrelated subbands. Each subband captures the characteristics of a certain scale and orientation of the original image. For each subband, we extract the standard deviation of the wavelet coefficients and therefore have a texture feature vector of length 10.

For water-filling edge-based structure feature vector, we first pass the original images through an edge detector to generate their corresponding edge map. We extract eighteen (18) elements from the edge maps, including *max fill time, max fork count, and so forth*. For a complete description of this edge feature vector, interested readers are referred to Zhou et al. (1999).

Dimension Reduction and PCA Splats

To create such a 2D layout, Principal Component Analysis (PCA) (Jolliffe, 1996) is first performed on the retrieved images to project the images from the high-dimensional feature space to the 2D screen. Image thumbnails are placed on the screen so that the screen distances reflect as closely as possible the similarities between the images. If the computed similarities from the high-dimensional feature space agree with our perception, and if the resulting feature dimension reduction preserves these similarities reasonably well, then the resulting spatial display should be informative and useful.

In our experiments, the 37 visual features (nine color moments, 10 wavelet moments and 18 water-filling features) are preextracted from the image database and stored off-line. Any 37-dimensional feature vector for an image, when taken in context with other images, can be projected onto the 2D screen based on the first two principal components normalized by the respective eigenvalues. Such a layout is denoted as a PCA Splat. We implemented both linear and nonlinear projection methods using PCA and Kruskal's algorithm (Torgeson, 1998). The projection using the nonlinear method such as the Kruskal's algorithm is an iterative procedure, slow to converge and converged to the local minima. Therefore the convergence largely depends on the initial starting point and cannot be repeated. On the contrary, PCA has several advantages over nonlinear methods like MDS. It is a fast, efficient and unique linear transformation that achieves the maximum distance preservation from the original high-dimensional feature space to 2D space among all possible linear transformations (Jolliffe, 1996). The fact that it fails to model nonlinear mappings (which MDS succeeds at) is in our opinion a minor compromise given the advantages of real-time, repeatable and mathematically tractable linear projections.

We should add that nonlinear dimensionality reduction (NLDR) by itself is a very large area of research and mostly beyond the scope of this chapter. We only comment on MDS because of its previous use by Rubner (1999) for CBIR. Use of other iterative NLDR techniques as "principal curves" or "bottleneck" auto-associative feedforward networks is usually prohibited by the need to perform real-time and repeatable projections. More recent advances such as IsoMap (Tennenbaum et al., 2000) and Local Linear Embedding (LLE) (Roweis & Saul, 2000) are also not amendable to real-time or closed-form computation. The most recent techniques such as Laplacian Eigenmaps (Belkin & Niyogi, 2003) and charting (Brand, 2003) have only just begun to be used and may promise advances useful in this

Figure 3. Top 20 retrieved images (ranked top to bottom and left to right; query is shown first in the list)

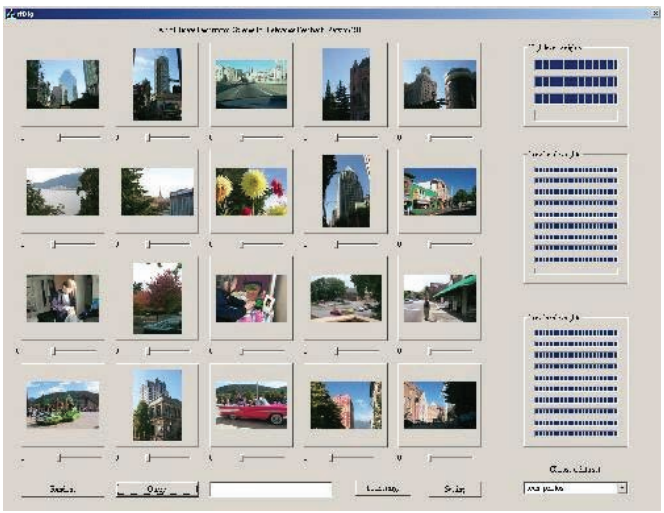

Figure 4. PCA Splat of top 20 retrieved images in Figure 3

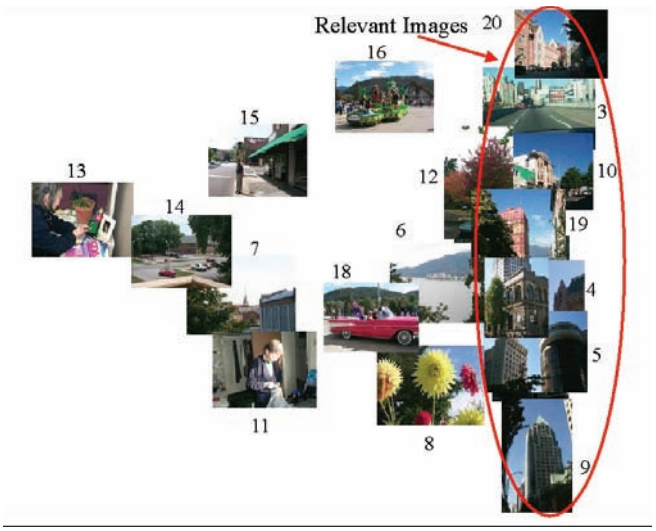


application domain, although we should hasten to add that the formulation of subspace weights and their estimation (see section on Context and User Modeling) is not as straightforward as with the case of linear dimension reduction (LDR) methods like PCA.

Let us consider a scenario of a typical image-retrieval engine at work in which an actual user is providing relevance feedback for the purposes of query refinement. Figure 3 shows an example of the retrieved images by the system (which resembles most traditional browsers in its 1D tile-based layout). The database is a collection of 534 images. The first image (building) is the query. The other nine relevant images are ranked in second, third, fourth, fifth, ninth, 10th, 17th, 19th and 20th places, respectively.

Figure 4 shows an example of a PCA Splat for the top 20 retrieved images shown in Figure 3. In addition to visualization by layout, in this particular example, the sizes (alternatively contrast) of the images are determined by their visual similarity to the query. The higher the rank, the larger is the size (or higher the contrast). There is also a number next to each image in Figure 4 indicating its corresponding rank in Figure 4. The view of query image, that is, the top left one in Figure 3, is blocked by the images ranked 19th, fourth, and 17th in Figure 4. A better view is achieved in Figure 7 after display optimization.

Clearly the relevant images are now better clustered in this new layout as opposed to being dispersed along the tiled 1D display in Figure 3. Additionally, PCA Splats convey N^2 mutual distance measures relating all pair-wise similarities between images, whereas the ranked 1D display in Figure 3 provides only N.

Display Optimization

However, one drawback of PCA Splat is that some images can be partially or totally overlapped, which makes it difficult to view all the images at the same time. The overlap will be even worse when the number of retrieved images becomes larger, for example, larger than 50. To solve the overlapping problem between the retrieved images, a novel optimized technique is proposed in this section.

Given a set the retrieved images and their corresponding sizes and positions, our optimizer tries to find a solution that places the images at the appropriate positions while deviating as little as possible from their initial PCA Splat positions. Assume the number of images is N. The image positions are represented by their center coordinates (x_i, y_i), $i = 1, ..., N$, and the initial image positions are denoted as (x^o_i, y^o_i), $i = 1, ..., N$. The minimum and maximum coordinates of the 2D screen are $[x_{min}, x_{max}, y_{min}, y_{max}]$. The image size is represented by its radius r_i for simplicity, $i = 1, ..., N$ and the maximum and minimum image size is r_{max} and r_{min} in radius, respectively. The initial image size is r^o_i, $i = 1, ..., N$.

To minimize the overlap, the images can be automatically moved away from each other to decrease the overlap between images, but this will increase the deviation of the images from their initial positions. Large deviation is certainly undesirable because the initial positions provide important information about mutual similarities between images. So there is a trade-off problem between minimizing overlap and minimizing deviation. Without increasing the overall deviation, an alternative way to minimize the overlap is to simply shrink the image size as needed, down to a minimum size limit. The image size will not be increased in the optimization process because this will always increase the overlap. For this reason, the initial image size r^o_i is assumed to be r_{max}.

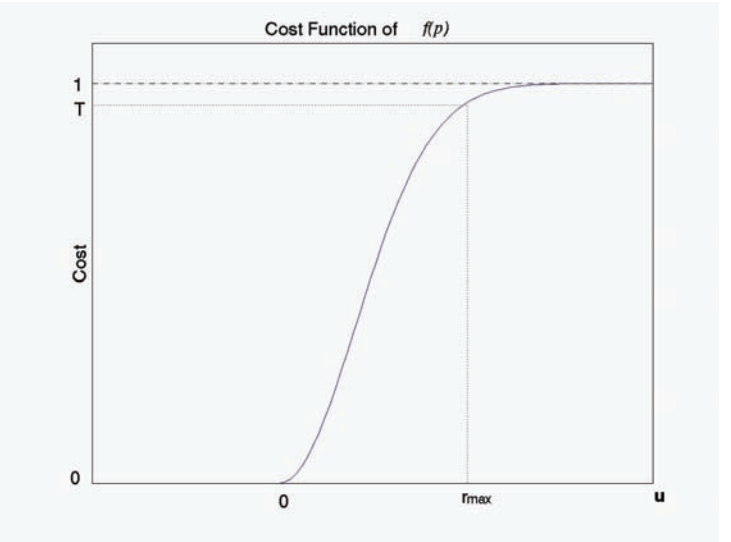
The total cost function is designed as a linear combination of the individual cost functions taking into account two factors. The first factor is to keep the overall overlap between the images on the screen as small as possible. The second factor is to keep the overall deviation from the initial position as small as possible.

$$J = F(p) + \lambda \cdot S \cdot G(p) \qquad (1)$$

where $F(p)$ is the cost function of the overall overlap and $G(p)$ is the cost function of the overall deviation from the initial image positions, S is a scaling factor which brings the range of $G(p)$ to the same range of $F(p)$, and S is chosen to be $(N–1)/2$. λ is a weight and $\lambda \geq 0$. When λ is zero, the deviation of images is not considered in overlapping minimization. When λ is less than one, minimizing overall overlap is more important than minimizing overall deviation, and vice versa for λ is greater than one.

The cost function of overall overlap is designed as

Figure 5. Cost function of overlap function f(p)



$$F(p) = \sum_{i=1}^{N} \sum_{j=i+1}^{N} f(p) \tag{2}$$

$$f(p) = \begin{cases} 1 - e^{-\frac{u^2}{\sigma_f}} & u > 0 \\ 0 & u \le 0 \end{cases} \tag{3}$$

where $u = r_i + r_j - \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}$, is a measure of overlapping. When $u \le 0$, there is no overlap between the i^{th} image and the j^{th} image, thus the cost is 0. When $u > 0$, there is partial overlap between the i^{th} image and the j^{th} image. When $u = 2 \cdot r_{max}$, the i^{th} image and the j^{th} image are totally overlapped. σ_f is a curvature-controlling factor.

Figure 5 shows the plot of $f(p)$. With the increasing value of $u (u > 0)$, the cost of overlap is also increasing.

From Figure 5, in Equation (3) is calculated by setting $T=0.95$ when $u = r_{max}$.

$$\sigma_f = \frac{-u^2}{\ln(1-T)}\Big|_{u=r_{\max}} \tag{4}$$

The cost function of overall deviation is designed as

$$G(p) = \sum_{i=1}^{N} g(p) \tag{5}$$

$$g(p) = 1 - e^{-\frac{v^2}{\sigma_g}} \tag{6}$$

where $v = \sqrt{(x_i - x_i^o)^2 + (y_i - y_i^o)^2}$, v is the measure of deviation of the i^{th} image from its initial position. σ_g is a curvature-controlling factor. (x_i, y_i) and (x^o_i, y^o_i) are the optimized and initial center coordinates of the i^{th} image, respectively, i = 1, ..., N.

Figure 6 shows the plot of $g(p)$. With the increasing value of v, the cost of deviation is also increasing.

From Figure 6, σ_g in Equation (6) is calculated by setting $T=0.95$ when $v = maxsep$. In our work, $maxsep$ is set to be $2 \cdot r_{max}$.

$$\sigma_g = \frac{-v^2}{\ln(1-T)}\Big|_{v=maxsep} \tag{7}$$

The optimization process is to minimize the total cost J by finding a (locally) optimal set of size and image positions. The nonlinear optimization method was implemented by an iterative gradient descent method (with line search). Once converged, the images will be redisplayed based on the new optimized sizes and positions.

Figure 6. Cost function of function g(p)

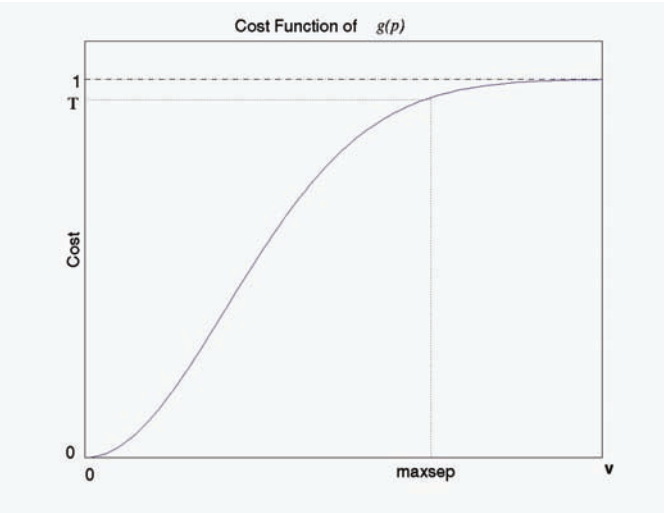


Figure 7. Optimized PCA Splat of Figure 3

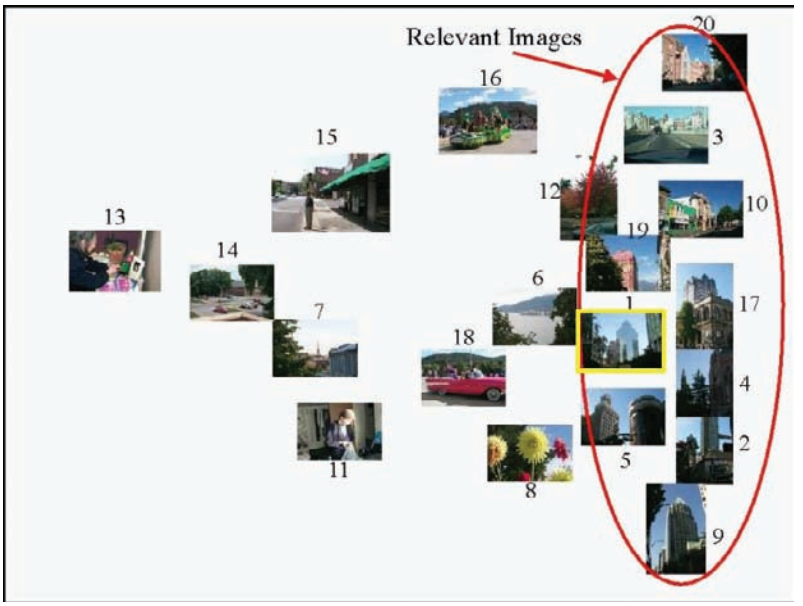

Figure 7 shows the optimized PCA Splats for Figure 3. The image with a yellow frame is the query image in Figure 3. Clearly, the overlap is minimized while the relevant images are still close to each other to allow a global view. With such a display, the user can see the relations between the images, better understand how the query performed, and subsequently formulate future queries more naturally. Additionally, attributes such as contrast and brightness can be used to convey rank. We note that this additional visual aid is essentially a third dimension of information display. For example, images with higher rank could be displayed with larger size or increased

brightness to make them stand out from the rest of the layout. An interesting example is to display "time" or "timeliness" by associating the size or brightness with how long ago the picture was taken, thus images from the "past" would appear smaller or dimmer than those taken recently. A full discussion of the resulting enhanced layouts is deferred to future work.

Also we should point out that despite our ability to "clean-up" layouts for maximal visibility with the optimizer we have designed, all subsequent figures in this chapter show Splats *without* any overlap minimization, because, for illustrating (as well as comparing) the accuracy of the estimation results in subsequent sections, the absolute position was necessary and important.

CONTEXT AND USER MODELING

Image content and "meaning" is ultimately based on semantics. The user's notion of content is a high-level concept, which is quite often removed by many layers of abstraction from simple low-level visual features. Even near-exhaustive semantic (keyword) annotations can never fully capture context-dependent notions of content. The same image can "mean" a number of different things depending on the particular circumstance. The visualization and browsing operation should be aware of which features (visual and/or semantic) are relevant to the user's current focus (or working set) and which should be ignored. In the space of all possible features for an image, this problem can be formulated as a subspace identification or feature weighting technique that is described fully in this section.

Estimation of Feature Weights

By user modeling or "context awareness" we mean that our system must be constantly aware of and adapting to the changing concepts and preferences of the user. A typical example of this human-computer synergy is having the system learn from a user-generated layout in order to visualize new examples based on identified relevant/irrelevant features. In other words, design smart browsers that "mimic" the user, and over time, adapt to their style or preference for browsing and query display. Given information from the layout, for example, positions and mutual distances between images, a novel feature weight estimation scheme, noted as α-estimation is proposed, where α is a weighting vector for features, for example, color, texture and structure (and semantic keywords).

We now describe the subspace estimation of α for visual features only, for example, color, texture, and structure, although it should be understood that the features could include visual, audio and semantic features or any hybrid combination thereof.

In theory, the estimation of weights can be done for all the visual features if given enough images in the layout. The mathematical formulation of this estimation problem follows.

The weighing vector is $\alpha = \{\alpha_1, \alpha_2, ..., \alpha_L\}$, where L is the total length of color, texture, and structure feature vector, for example, $L = 37$ in this chapter. The number of images in the preferred clustering is N, and X is an $L \times N$ matrix where the i^{th} column is the feature vector of the i^{th} image, i, $j = 1, ..., N$. The distance, for example Euclidean-based between the i^{th} image and the j^{th} image, for $i, j = 1, ..., N$, in the preferred clustering (distance in 2D space) is d_{ij}. These weights $\alpha_1, \alpha_2, ..., \alpha_L$ are constrained such that they always sum to 1.

We then define an energy term to minimize with an L_p norm (with $p = 2$). This cost function is defined in Equation (8). It is a nonnegative quantity that indicates how well mutual distances are preserved in going from the original high-dimensional feature space to 2D space. Note that this cost function is similar to MDS stress, but unlike MDS, the minimization is seeking the optimal feature weights α. Moreover, the low-dimensional projections in this case are already known. The optimal weighting parameter recovered is then

used to weight original feature-vectors before applying a PCA Splat which will result in the desired layout.

$$J = \sum_{i=1}^{N}\sum_{j=1}^{N}(d_{ij}{}^{p} - \sum_{k=1}^{L}\alpha_k{}^{p} \mid \mathbf{X}_i{}^{(k)} - \mathbf{X}_j{}^{(k)} \mid^{p})^2 \quad (8)$$

The global minimum of this cost function corresponding to the optimal weight parameter α, is easily obtained using a constrained (non-negative) least-squares. To minimize *J*, take the partial derivative of *J* relative to for $l = 1, ..., L$ and set them to zero, respectively.

$$\frac{\partial J}{\partial \alpha_l{}^{p}} = 0 \qquad l = 1, \cdots, L \quad (9)$$

We thus have

$$\sum_{k=1}^{L}\alpha_k{}^{p}\sum_{i=1}^{N}\sum_{j=1}^{N}|\mathbf{X}_i{}^{(l)} - \mathbf{X}_j{}^{(l)}|^{p}|\mathbf{X}_i{}^{(k)} - \mathbf{X}_j{}^{(k)}|^{p} = \sum_{i=1}^{N}\sum_{j=1}^{N} d_{ij}{}^{p} \mid \mathbf{X}_i{}^{(l)} - \mathbf{X}_j{}^{(l)}|^{p}$$

$$l = 1, \cdots, L \quad (10)$$

Define

$$R(l, k) = \sum_{i=1}^{N}\sum_{j=1}^{N} \mid \mathbf{X}_i{}^{(l)} - \mathbf{X}_j{}^{(l)} \mid^{p} \mid \mathbf{X}_i{}^{(k)} - \mathbf{X}_j{}^{(k)} \mid^{p} \quad (11)$$

$$r(l) = \sum_{i=1}^{N}\sum_{j=1}^{N} d_{ij}{}^{p} \mid \mathbf{X}_i{}^{(l)} - \mathbf{X}_j{}^{(l)} \mid^{p} \quad (12)$$

and subsequently simplify Equation (10) to:

$$\sum_{k=1}^{L}\alpha_k{}^{p} R(l, k) = r(l) \quad l = 1, \cdots, L \quad (13)$$

Using the following matrix/vector definitions

$$R = \begin{bmatrix} R(1,1) & R(1,2) & \cdots & R(1, L) \\ R(2,1) & R(2,2) & \cdots & R(2,L) \\ \vdots & \vdots & \vdots & \vdots \\ R(L,1) & R(L,2) & \cdots & R(L,L) \end{bmatrix}$$

$$\beta = \begin{bmatrix} \alpha_1{}^{p} \\ \alpha_2{}^{p} \\ \vdots \\ \alpha_L{}^{p} \end{bmatrix}$$

and

$$r = \begin{bmatrix} r(1) \\ r(2) \\ \vdots \\ r(L) \end{bmatrix}$$

Equation (13) is simplified to

$$R \cdot \beta = r \quad (14)$$

Subsequently β is obtained as a constrained ($\beta > 0$) linear least-squares solution of the above system. The weighting vector α_k is then simply determined by the *p-th* root of β where we typically use *p=2.*

We note that there is an alternative approach to estimating the subspace weighting vector α in the sense of *minimum deviation*, which we have called "deviation-based" α-estimation. The cost function in this case is defined as follows:

$$J = \sum_{i=1}^{N} \mid p^{(i)}(x, y) - \hat{p}^{(i)}(x, y) \mid^{2} \quad (15)$$

where $p^{(i)}(x,y)$ and are the original and projected 2D locations of the i^{th} image, respectively. This formulation is a more direct approach to estimation since it deals with the final position of the images in the layout. Unfortunately, however, this approach requires the simultaneous estimation of both the weight vectors as well as the projection basis and consequently requires less-accurate iterative *re-estimation* techniques (as opposed to more robust closed-form solutions possible with Equation (8)). A full derivation of the solution for our deviation-based α estimation is shown in Appendix A.

Compare two different estimation methods: stress-based and deviation-based. The former is most useful, robust, and "identifiable" in the control theory sense of the word. The latter uses a somewhat unstable re-estimation framework and does not always give satisfactory results. However, we still provide a detailed description for the sake of completeness. The shortcomings of this latter method are immediately apparent from the solution requirements. This discussion can be found in Appendix A.

For the reasons mentioned above, in all the experiments reported in this chapter, we use only the stress-based method of Equation (8) for α estimation.

We note that in principle it is possible to use a single weight for each dimension of the feature vector. However, this would lead to a poorly determined estimation problem since it is unlikely (and/or undesirable) to have that many sample images from which to estimate all individual weights. Even with plenty of examples (an over-determined system), chances are that the estimated weights would generalize poorly to a new set of images — this is the same principle used in a modeling or regression problem where the order of the model or number of free parameters should be less than the number of available observations.

Therefore, in order to avoid the problem of *over-fitting* and the subsequent poor generalization on new data, it is ideal to use fewer weights. In this respect, the less weights (or more subspace "groupings") there are, the better the generalization performance. Since the origin of all visual features, that is, 37 features, is basically from three different (independent) visual attributes: color, texture and structure, it seems prudent to use three weights corresponding to these three subspaces. Furthermore, this number is sufficiently small to almost guarantee that we will always have enough images in one layout from which to estimate these three weights. Therefore, in the remaining portion of the chapter, we only estimated a weighting vector , where α_c is the weight for color feature of length L_c, α_t is the weight for texture feature of length L_t, α_s and is the weight for structure feature of length , respectively. These weights α_c, α_t, α_s are constrained such that they always sum to 1, and $L = L_c + L_t + L_s$.

Figure 8 shows a simple user layout where three car images are clustered together despite their different colors. The same is performed with three flower images (despite their texture/structure). These two clusters maintain a sizeable separation, thus suggesting two separate concept classes implicit by the user's placement. Specifically, in this layout the user is clearly concerned with the distinction between *car* and *flower* regardless of color or other possible visual attributes.

Applying the α-estimation algorithm to Figure 8, the feature weights learned from this layout are $\alpha_c = 0.3729$, $\alpha_t = 0.5269$ and $\alpha_s = 0.1002$. This

Figure 8. An example of a user-guided layout

Figure 9. PCA Splat on a larger set of images using (a) estimated weights (b) arbitrary weights

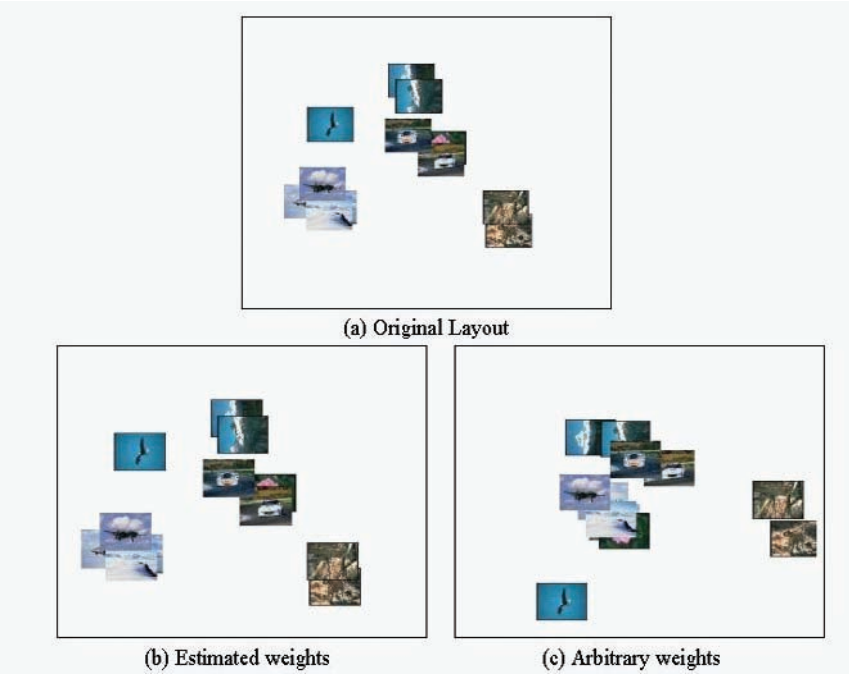
(a) *(b)*

shows that the most important feature in this case is texture and not color, which is in accord with the concepts of car versus flower as graphically indicated by the user in Figure 8.

Now that we have the learned feature weights (or modeled the user) what can we do with them? Figure 9 shows an example of a typical application: automatic layout of a larger (more complete data set) set of images in the style indicated by the user. Figure 9(a) shows the PCA Splat using the learned feature weight for 18 cars and 19 flowers. It is obvious that the PCA Splat using the estimated weights captures the essence of the configuration layout in Figure 8. Figure 9(b) shows a PCA Splat of the same images but with a randomly generated α, denoting an arbitrary but coherent 2D layout, which in this case, favors color ($\alpha_c = 0.7629$). This comparison reveals that proper feature weighting is an important factor in generating the user-desired and sensible layouts. We should point out that a random α does not generate a random layout, but rather one that is still coherent, displaying consistent groupings or clustering. Here we have used such "random" layouts as substitutes for alternative (arbitrary) layouts that are nevertheless "valid" (differing only in the relative contribution of the three features to the final design of the layout). Given the difficulty of obtaining hundreds (let alone thousands) of real user layouts that are needed for more complete statistical tests (such as those in the next section), random α layouts are the only conceivable way of "simulating" a layout by a real user in accordance with "familiar" visual criteria such as color, texture or structure.

Figure 10(a) shows an example of another layout. Figure 10(b) shows the corresponding computer-generated layout of the same images with their high-dimensional feature vectors weighted by the estimated α, which is recovered solely from the 2D configuration of Figure 10(a). In this instance the reconstruction of the layout is near perfect, thus demonstrating that our high-dimensional subspace feature weights can in fact

Figure 10. (a) An example layout. Computer-generated layout based on (b) reconstruction using learned feature weights, and (c) the control (arbitrary weights)



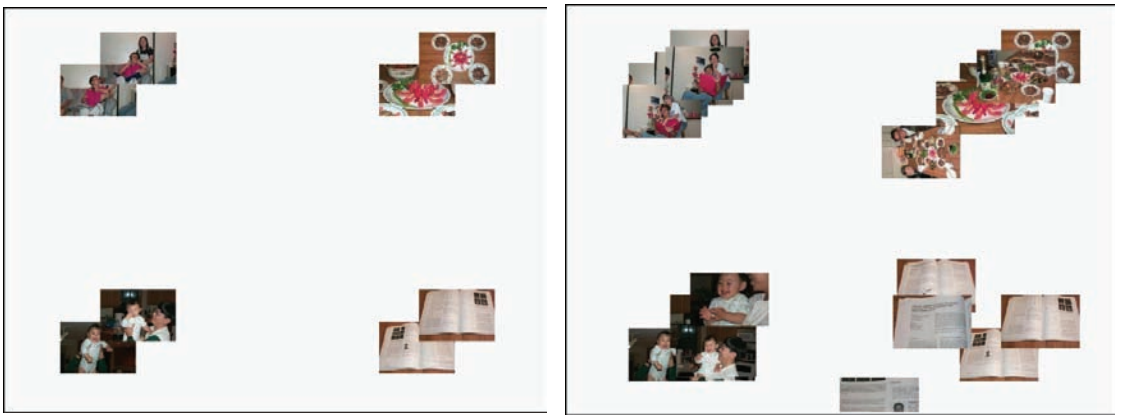
be recovered from pure 2D information. For comparison, Figure 10(c) shows the PCA Splat of the same images with their high-dimensional feature vectors weighted by a random α.

Figure 11 shows another example of user-guided layout. Assume that the user is describing her family story to a friend. In order not to disrupt the conversational flow, she only lays out a few photos from her personal photo collections and expects the computer to generate a similar and consistent layout for a larger set of images from the same collection. Figure 11(b) shows the computer-generated layout based on the learned feature weights from the configuration of Figure 11(a). The computer-generated layout is achieved using the α-estimation scheme and postlinear, for example, affine transform or nonlinear transformations. Only the 37 visual features (nine color moments (Stricker & Orengo 1995), 10 wavelet moments (Smith & Chang, 1994) and 18 water-filling features (Zhou et al., 1999)) were used for this PCA Splat. Clearly the computer-generated layout is similar to the user layout with the visually similar images positioned at the user-indicated locations. We should add that in this example no semantic features (keywords) were used, but it is clear that their addition would only enhance such a layout.

STATISTICAL ANALYSIS

Given the lack of sufficiently large (and willing) human subjects, we undertook a Monte Carlo approach to testing our user-modeling and estimation method. Monte Carlo simulation (Metropolis & Ulam, 1949) randomly generates values for uncertain variables over and over to simulate a model. Thereby simulating 1000 computer generated layouts (representing ground-truth values of α's), which were meant to emulate 1000 actual userlayouts or preferences. In each case, α estima-

Figure 11: Usermodeling for automatic layout. (a) a user-guided layout: (b) computer layout for larger set of photos (four classes and two photos from each class)



(a) *(b)*

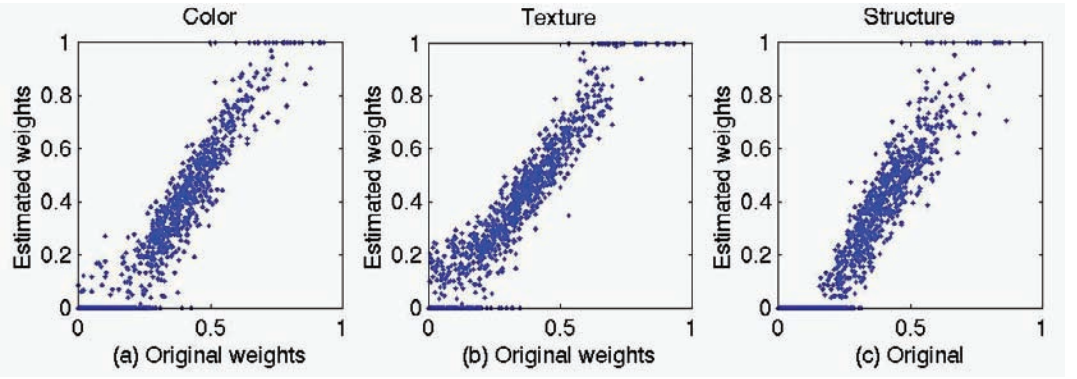
tion was performed to recover the original values as best as possible. Note that this recovery is only partially effective due to the information loss in projecting down to a 2D space. As a control, 1000 randomly generated feature weights were used to see how well they could match the user layouts (i.e., by chance alone).

Our primary test database consists of 142 images from the COREL database. It has 7 categories of car, bird, tiger, mountain, flower, church and airplane. Each class has about 20 images. Feature extraction based on color, texture and structure has been done off-line and prestored. Although we will be reporting on this test data set — due to its common use and familiarity to the CBIR community — we should emphasize that we have also successfully tested our methodology on larger and much more heterogeneous image libraries. (For example, real personal photo collections of 500+ images, including family, friends, vacations, etc.). Depending on the particular domain, one can obtain different degrees of performance, but one thing is for sure: for narrow application domain (for example, medical, logos, trademarks, etc.) it is quite easy to construct systems which work extremely well, by taking advantages of the limiting constraints in the imagery.

The following is the Monte Carlo procedure that was used for testing the significance and validity of user modeling with α estimation:

1. Randomly select *M* images from the database. Generate arbitrary (random) feature weights α in order to simulate a "user" layout.
2. Do a PCA Splat using this "ground truth" α.
3. From the resulting 2D layout, estimate α and denote the estimated α as .
4. Select a new distinct (nonoverlapping) set of *M* images from the database.
5. Do PCA Splats on the second set using the original α, the estimated , and a third random α' (as control).
6. Calculate the resulting stress in Equation (8), and layout deviation (2D position error) in Equation (9) for the original, estimated and random (control) values of α, , and α', respectively.
7. Repeat 1,000 times.

Figure 12. Scatter plot of estimation, estimated weights versus original weights



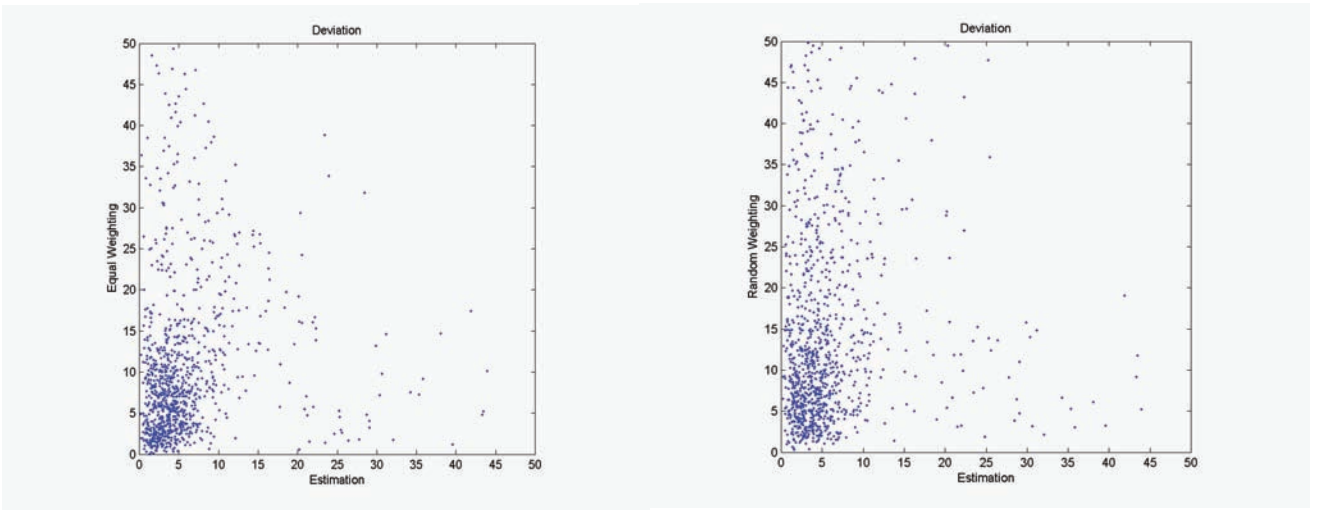
The scatter plot of α estimation is shown in Figure 12. Clearly there is a direct linear relationship between the original weights α and the estimated weights . Note that when the original weight is very small (<0.1) or very large (>0.9), the estimated weight is zero or one correspondingly. This means that when one particular feature weight is very large (or very small), the corresponding feature will become the most dominant (or least dominant) feature in the PCA, therefore the estimated weight for this feature will be either one or zero. This "saturation" phenomenon in Figure 12 is seen to occur more prominently for the case of structure (lower left of the rightmost panel) that is possibly more pronounced because of the structure feature vector being so (relatively) high dimensional. Additionally, structure features are not as well defined compared with color and texture (e.g., they have less discriminating power).

In terms of actual measures of stress and deviation we found that the α-estimation scheme yielded the smaller deviation 78.4% of the time and smaller stress 72.9%. The main reason these values are less than 100% is due to the nature of the Monte Carlo testing and the fact that working with low-dimensional (2D) spaces, random weights can be close to the original weights and hence can often generate similar "user" layouts (in this case apparently about 25% of the time).

We should add that an alternative "control" or null hypothesis to that of random weights α = is that of fixed equal weights. This "weighting" scheme corresponds to the assumption that there are to be no preferential biases in the subspace of the features, that they should all count equally in forming the final layout (or default PCA). But the fundamental premise behind the chapter is that there is a change or variable bias in the relative importance of the different features as manifested by different user layout and styles. In fact, if there was to be no bias in the weights (i.e., they were set equal) then there would be no usermodeling or adaptation necessary since there would always be just one type or "style" of layout (the one resulting from equal weights). In order to understand this question fully, we compare the results of random weights versus equal weights (compared to the estimation framework advocated).

In an identical set of experiments, replacing random weights for comparison layouts with equal weights $\alpha = \{\frac{1}{3}, \frac{1}{3}, \frac{1}{3}\}^T$, we found a similar distribution of similarity scores. In particular, since the goal is obtaining accurate 2D layouts where positional accuracy is critical, we look at the resulting deviation in the case of both random weights and equal weight versus estimated weights. We carry out a large Monte Carlo experiments (10,000 trials) and Figure 13 shows the scatter plot of the

Figure 13. Scatter plot of deviation scores (a) equal weights (y-axis) versus estimation weights (x-axis) (b) random weights (y-axis) versus estimated weights (x-axis)



(a) Equal versus estimated

(b) Random versus estimated

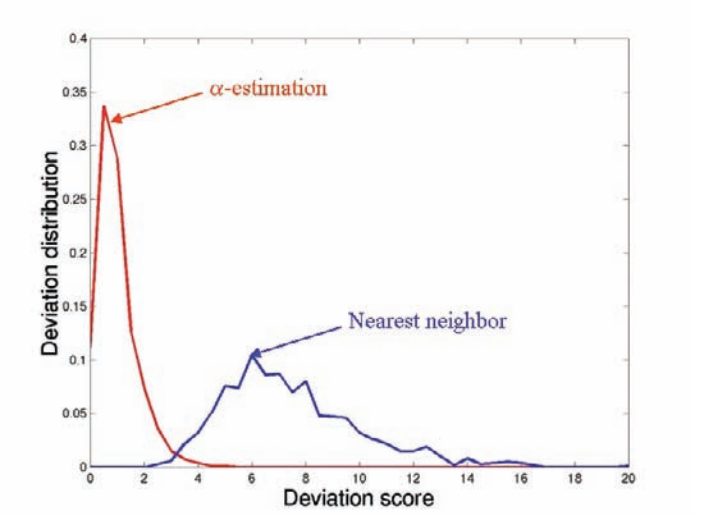
deviation scores. Points above the diagonal (not shown) indicate a deviation performance worse than that of weight estimation. As can be seen here, the test results are roughly comparable for equal and random weights.

In Figure 13, we noted that the α-estimation scheme yielded the smaller deviation 72.6% of the time compared to equal weights (as opposed to the 78.4% compared with random weights). We therefore note that the results and conclusions of these experiments are consistent despite the choice of equal or random controls, and ultimately direct α estimation of a "user" layout is best.

Finally we should note that all weighting schemes (random or not) define sensible or "coherent" layouts. The only difference is in the amount by which color, texture and structure is emphasized. Therefore even random weights generate "nice" or pleasing layouts, that is, random weights do not generate random layouts.

Another control other than random (or equal) weights is to compare the deviation of an α-estimation layout generator to a simple scheme which assigns each new image to the 2D location of its (un-weighted or equally weighted) 37-dimensional nearest neighbor (NN) from the set of images previously laid out by the "user." This control scheme essentially operates on the principle that new images should be positioned on screen at the same location as their nearest neighbors in the original 37-dimensional feature space (the default similarity measure in the absence of any prior bias) and thus essentially ignores the operating subspace defined by the "user" in a 2D layout. The NN placement scheme would place the test picture, despite their similarity score, directly on top of whichever image, currently on the "table", that it is closest to. To do otherwise, for example to place it slightly shifted away, and so forth, would simply imply the existence of a nondefault "smart" projection function which defeats the purpose of

Figure 14. Comparison of the distribution of a-estimation versus nearest-neighbor deviation scores



this "control." The point of this particular experiment is to compare our "smart" scheme with one which has no knowledge or preferential subspace weightings and see how this would subsequently map to (relative) position on the display. The idea behind that is that a dynamic user-centric display should adapt to varying levels of emphasis to color, texture, and structure.

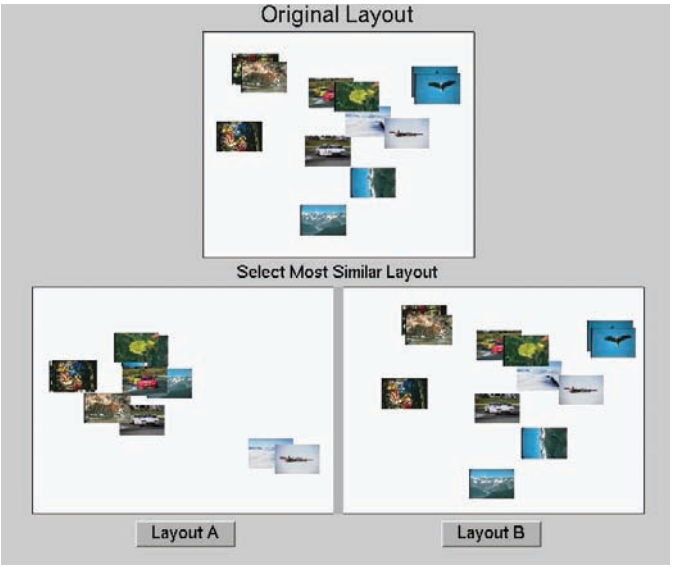
The distributions of the outcomes of this Monte Carlo simulation are shown in Figure 14 where we see that the layout deviation using α estimation (red: $\mu = 0.9691$, $\sigma = 0.7776$) was consistently lower — by almost an order of magnitude — than the nearest neighbor layout approach (blue: $\mu = 7.5921$ $\sigma = 2.6410$). We note that despite the noncoincident overlap of the distributions' tails in Figure 14, in every one of the 1,000 random trials the α-estimation deviation score was found to be smaller than that of nearest-neighbour (a key fact not visible in such a plot).

USER PREFERENCE STUDY

In addition to the computer-generated simulations, we have in fact conducted a preliminary user study that has also demonstrated the superior performance of α estimation over random feature weighting used as a control. The goal was to test whether the estimated feature weights would generate a better layout on a *new* but similar set of images than random weightings (used as control). The user interface is shown in Figure 15 where the top panel is a coherent layout generated by a random α on reference image set. From this layout, an estimate of α was computed and used to redo the layout. A layout generated according to random weights was also generated and used as a control. These two layouts were then displayed in the bottom panels with randomized (A vs. B) labels (in order to remove any bias in the presentation). The user's task was to select which layout (A or B) was more similar to the reference layout in the top panel.

In our experiment, six naïve users were instructed in the basic operation of the interface and given the following instructions: (1) both absolute and relative positions of images matter, (2) in general, similar images, like cars, tigers, and so forth, should cluster and (3) the relative positions of the clusters also matter. Each user performed 50 forced-choice tests with no time limits. Each test set of 50 contained redundant (randomly recurring) tests in order to test the user's consistency.

Figure 15. α-estimation-matters user test interface



We specifically aimed at not "priming" the subjects with very detailed instructions (such as, "It's not valid to match a red car and a red flower because they are both red."). In fact, the "naïve" test subjects were told nothing at all about the three feature types (color, texture, structure), the associated α or obviously the estimation technique. In this regard, the paucity of the instructions was entirely intentional: whatever mental grouping that seemed valid to them was the key. In fact, this very same flexible association of the user is what was specifically tested for in the *consistency* part of the study.

Table 1 shows the results of this user study. The average preference indicated for the α-estimation-based layout was found to be 96% and an average consistency rate of a user was 97%. We note that the α-estimation method of generating a layout in a similar "style" to the reference was consistently favored by the users. A similar experimental study has shown this to also be true even if the test layouts consist of *different* images than those used in the reference layout (i.e., similar but not identical images from the same categories or classes).

DISCUSSIONS AND FUTURE WORK

We have designed our system with general CBIR in mind but more specifically for personalized photo collections. An optimized content-based visualization technique is proposed to generate a 2D display of the retrieved images for content-based image retrieval. We believe that both the computational results and the pilot user study support our claims of a more perceptually intuitive and informative visualization engine that not only provides a better understanding of query retrievals but also aids in forming new queries.

The proposed content-based visualization method can be easily applied to project the images from high-dimensional feature space to a 3D space for more advanced visualization and navigation. Features can be multimodal, expressing individual visual features, for example, color

Table 1. Results of user-preference study

	P reference for estimates	Preference for random weights	User's consistency rate
User 1	90%	10%	100%
User 2	98%	2 %	90%
User 3	98%	2 %	90%
User 4	95%	5 %	100%
User 5	98%	2 %	100%
User 6	98%	2 %	100%

alone, audio features and semantic features, for example, keywords, or any combination of the above. The proposed layout optimization technique is also quite general and can be applied to avoid overlapping of any type of images, windows, frames or boxes.

The PDH project is at its initial stage. We have just begun our work in both the user interface design and photo visualization and layout algorithms. The final visualization and retrieval interface can be displayed on a computer screen, large panel projection screens, or, for example, on embedded tabletop devices (Shen et al., 2001; Shen et al., 2003) designed specifically for purposes of storytelling or multiperson collaborative exploration of large image libraries.

Many interesting questions still remain as our future research in the area of content-based information visualization and retrieval. The next task is to carry out an extended user-modeling study by having our system learn the feature weights from various sample layouts provided by the user. We have already developed a framework to incorporate visual features with semantic labels for both retrieval and layout.

Another challenging area is automatic "summarization" and display of large image collections. Since summarization is implicitly defined by user preference, a estimation for user modeling will play a key role in this and other high-level tasks where context is defined by the user.

Finally, incorporation of relevance feedback for content-based image retrieval based on the visualization of the optimized PCA Splat seems very intuitive and is currently being explored. By manually grouping the relevant images together at each relevance feedback step, a dynamic user-modeling technique will be proposed.

APPENDIX A

Let

$$\mathbf{P}_i = p^{(i)}(x,y) = \begin{pmatrix} x_i \\ y_i \end{pmatrix}$$

and

$$\hat{\mathbf{P}}_i = \hat{p}^{(i)}(x,y) = \begin{pmatrix} \hat{x}_i \\ \hat{y}_i \end{pmatrix},$$

and Equation (15) is rewritten as

$$J = \sum_{i=1}^{N} \| \mathbf{P}_i - \hat{\mathbf{P}}_i \|^2 \qquad \text{(A.1)}$$

Let $\mathrm{X_i}$ be the column feature vector of the i^{th} image, where

$$\mathbf{X}_i = \begin{bmatrix} \mathbf{X}_c^{(i)} \\ \mathbf{X}_t^{(i)} \\ \mathbf{X}_s^{(i)} \end{bmatrix},$$

$i = 1, \cdots, N$. $\mathbf{X}_c^{(i)}$, $\mathbf{X}_t^{(i)}$ and $\mathbf{X}_s^{(i)}$ are the corresponding color, texture and structure feature vector of the i^{th} image and their lengths are L_c, L_t and L_s, respectively. Let

$$\mathbf{X}'_{\mathrm{i}} = \begin{pmatrix} \alpha_{\mathrm{c}}\mathbf{X}_{\mathrm{c}}^{(\mathrm{i})} \\ \alpha_{\mathrm{t}}\mathbf{X}_{\mathrm{t}}^{(\mathrm{i})} \\ \alpha_{\mathrm{s}}\mathbf{X}_{\mathrm{s}}^{(\mathrm{i})} \end{pmatrix}$$

be the weighted high-dimensional feature vector. These weights α_c, α_t, α_s are constrained such as they always sum to 1.

$\hat{\mathbf{P}}_i$ is estimated by linearly projecting the weighted high-dimensional features to 2D. Let $\mathrm{X} = [\mathrm{X}_1, \mathrm{X}_2, ..., \mathrm{X}_N]$, it is an $L \times N$ matrix, where $L = L_c + L_t + L_s$. $\hat{\mathbf{P}}_i$ is estimated by

$$\hat{\mathbf{P}}_{\mathrm{i}} = U^T(\mathbf{X}'_{\mathrm{i}} - \mathbf{X}_{\mathrm{m}})\, i = 1, \cdots, N \qquad \text{(A.2)}$$

where U is a $L \times 2$ projection matrix, X_{m} is an $L \times 1$ mean column vector of X'_{i}, $i = 1, ..., N$. Substitute $\hat{\mathbf{P}}_i$ by Equation (A.2) into Equation (A.1), the problem is therefore one of seeking the optimal feature weights α, projection matrix U, and column vector X_m such as J in Equation (A.3) is minimized, given X_{i}, P_{i}, $i = 1, ..., N$.

$$J = \sum_{i=1}^{N} \| U^T(\mathbf{X}'_{\mathrm{i}} - \mathbf{X}_m) - \mathbf{P}_{\mathrm{i}} \|^2 \qquad \text{(A.3)}$$

In practice, it is almost impossible to estimate optimal α, U and X_{m} simultaneously based on the limited available data X_{i}, P_{i}, $i = 1, ..., N$. We thus make some modifications. Instead of estimating α, U and X_m simultaneously, we modified the estimation process to be a two-step *re-estimation* procedure. We first estimate the projection matrix U and column vector X_m, and then estimate feature weight vector α based on the computed U and X_m, and iterate until convergence.

Let $U^{(0)}$ be the eigenvectors corresponding to the largest two eigenvalues of the covariance matrix of $\mathbf{X}$, where $\mathrm{X} = [\mathrm{X}_1, \mathrm{X}_2, ..., \mathrm{X}_N]$, is the mean vector of $\mathbf{X}$.

We have

$$\mathbf{P}_{\mathrm{i}}^{(0)} = (U^{(0)})^T(\mathbf{X}_{\mathrm{i}} - \mathbf{X}_{\mathrm{m}}^{(0)}) \qquad \text{(A. 4)}$$

$\mathbf{P}_{\mathrm{i}}^{(0)}$ is the projected 2D coordinates of the unweighted high-dimensional feature vector of the i^{th} image. Ideally its target location is $\mathbf{P}_{\mathrm{i}}$. To consider the alignment correction, a rigid transform (Zwillinger, 1995) is applied.

$$\hat{\mathbf{P}}_{\mathrm{i}}^{(0)} = A \cdot \mathbf{P}_{\mathrm{i}}^{(0)} + T \qquad \text{(A. 5)}$$

where A is a 2×2 matrix and T is a 2×1 vector. A, T are obtained by minimizing the L_2-norm of $\mathbf{P}_{\mathrm{i}} - \hat{\mathbf{P}}_{\mathrm{i}}^{(0)}$.

Therefore J in Equation (A. 3) is modified to

$$J = \sum_{i=1}^{N} \| AU^{(0)}(\mathbf{X}'_i - \mathbf{X}_{\mathrm{m}}^{(0)}) - (\mathbf{P}_{\mathrm{i}} - T) \|^2 \qquad \text{(A. 6)}$$

Let $U = UA^{(0)}$, $\mathbf{X}_m = \mathbf{X}_{\mathrm{m}}^{(0)}$ and $\mathbf{P}_{\mathrm{i}} = \mathbf{P}_{\mathrm{i}} - T$, we still have the form of Equation (A. 3).

Let us rewrite

$$U^T = \begin{bmatrix} U_{11}, \cdots U_{1(L_c+L_t+L_s)} \\ U_{21}, \cdots, U_{2(L_c+L_t+L_s)} \end{bmatrix}$$

After some simplifications on Equation (A. 3), we have

$$J = \sum_{i=1}^{N} \| \alpha_c A_i + \alpha_t B_i + \alpha_s C_i - D_i \|^2 \qquad \text{(A. 7)}$$

where

$$A_i = \begin{bmatrix} \sum_{k=1}^{L_c} U_{1k}\mathbf{X}_c^{(k)}(i) \\ \sum_{k=1}^{L_c} U_{2k}\mathbf{X}_c^{(k)}(i) \end{bmatrix} \qquad B_i = \begin{bmatrix} \sum_{k=1}^{L_t} U_{1(k+L_c)}\mathbf{X}_t^{(k)}(i) \\ \sum_{k=1}^{L_t} U_{2(k+L_t)}\mathbf{X}_t^{(k)}(i) \end{bmatrix}$$

$$C_i = \begin{bmatrix} \sum_{k=1}^{L_s} U_{1(k+L_c+L_t)}\mathbf{X}_s^{(k)}(i) \\ \sum_{k=1}^{L_s} U_{2(k+L_c+L_t)}\mathbf{X}_s^{(k)}(i) \end{bmatrix}$$

and $D_i = U^T\mathbf{X}_m + \mathbf{P}_i$,

A_i, B_i, C_i and D_i are the 2×1feature vectors, respectively.

To minimize J, we take the partial derivatives of J relative to α_c, α_t, α_s and set them to zero, respectively.

$$\begin{aligned} \frac{\partial J}{\partial \alpha_c} &= 0 \\ \frac{\partial J}{\partial \alpha_t} &= 0 \\ \frac{\partial J}{\partial \alpha_s} &= 0 \end{aligned} \quad \text{(A. 8)}$$

We thus have:

$$E \cdot \boldsymbol{\alpha} = f \quad \text{(A. 9)}$$

where

$$E = \begin{bmatrix} \sum_{i=1}^{N} A_i^T A_i & \sum_{i=1}^{N} A_i^T B_i & \sum_{i=1}^{N} A_i^T C_i \\ \sum_{i=1}^{N} B_i^T A_i & \sum_{i=1}^{N} B_i^T B_i & \sum_{i=1}^{N} B_i^T C_i \\ \sum_{i=1}^{N} C_i^T A_i & \sum_{i=1}^{N} C_i^T B_i & \sum_{i=1}^{N} C_i^T C_i \end{bmatrix},$$

$$f = \begin{bmatrix} \sum_{i=1}^{N} A_i^T D_i \\ \sum_{i=1}^{N} B_i^T D_i \\ \sum_{i=1}^{N} C_i^T D_i \end{bmatrix}$$

and α is obtained by solving the linear Equation (A.9).

ABSTRACT

This chapter is intended to disseminate the concept of digital signature-based image authentication. Capabilities of digital signature-based image authentication and its superiority over watermarking-based approaches are described first. Subsequently, general models of this technique — strict authentication and non-strict authentication are introduced. Specific schemes of the two general models are also reviewed and compared. Finally, based on the review, design issues faced by the researchers and developers are outlined.

INTRODUCTION

In the past decades, the technological advances of international communication networks have facilitated efficient digital image exchanges. However, the availability of versatile digital signal/image processing tools has also made image duplication trivial and manipulations discernable for the human visual system (HVS). Therefore, image authentication and integrity verification have become a popular research area in recent years. Generally, image authentication is projected as a procedure of guaranteeing that the image content has not been altered, or at least that the visual (or semantic) characteristics of the image are maintained after incidental manipulations such as JPEG compression. In other words, one of the objectives of image authentication is to verify the integrity of the image. For many applications such as medical archiving, news reporting and political events, the capability of detecting manipulations of digital images is often required. Another need for image authentication arises from the requirement of checking the identity of the image sender. In the scenario that a buyer wants to purchase and receive an image over the networks, the buyer may obtain the image via e-mails or from the

Internet-attached servers that may give a malicious third party the opportunities to intercept and manipulate the original image. So the buyer needs to assure that the received image is indeed the original image sent by the seller. This requirement is referred to as the *legitimacy* requirement in this chapter.

To address both the integrity and legitimacy issues, a wide variety of techniques have been proposed for image authentication recently. Depending on the ways chosen to convey the authentication data, these techniques can be roughly divided into two categories: *labeling-based techniques* (e.g., the method proposed by Friedman, 1993) and *watermarking-based techniques* (e.g., the method proposed by Walton, 1995). The main difference between these two categories of techniques is that labeling-based techniques create the authentication data in a separate file while watermarking-based authentication can be accomplished without the overhead of a separate file. However, compared to watermarking-based techniques, labeling-based techniques potentially have the following advantages.

- They can detect the change of every single bit of the image data if strict integrity has to be assured.
- The image authentication can be performed in a secure and robust way in public domain (e.g., the Internet).
- The data hiding capacity of labeling-based techniques is higher than that of watermarking.

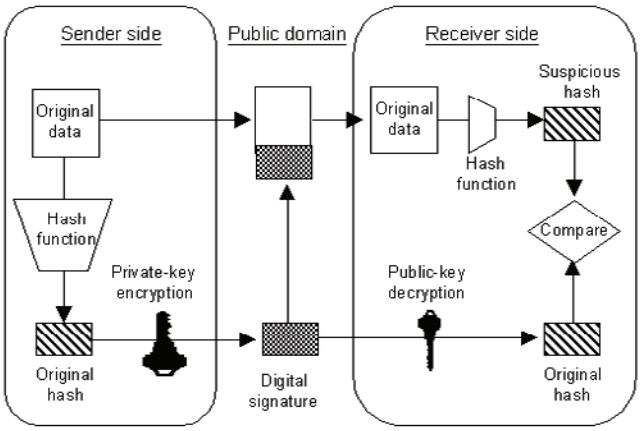
Given its advantages on watermarking-based techniques, we will focus on labeling-based authentication techniques.

In labeling-based techniques, the authentication information is conveyed in a separate file called *label*. A label is additional information associated with the image content and can be used to identify the image. In order to associate the label content with the image content, two different ways can be employed and are stated as follows.

- The first methodology uses the functions commonly adopted in message authentication schemes to generate the authentication data. The authentication data are then encrypted with secret keys or private keys depending on what cryptographic authentication protocol is employed. When applying to two different bit-streams (i.e., different authentication data), these functions can produce two different bit sequences, in such a way that the change of every single bit of authentication data can be detected. In this chapter, image authentication schemes of this class are referred to as *strict authentication.*
- The second methodology uses some special-purpose functions to extract essential image characteristics (or *features*) and encrypt them with senders' private keys (Li, Lou & Chen, 2000; Li, Lou & Liu, 2003). This procedure is the same as the digital signature protocol except that the features must be designed to compromise with some specific image processing techniques such as JPEG compression (Wallace, 1991). In this chapter, image authentication techniques of this class are referred to as *non-strict authentication.*

The strict authentication approaches should be used when strict image integrity is required and no modification is allowed. The functions used to produce such authentication data (or *authenticators*) can be grouped into three classes: *message encryption, message authentication code* (MAC), and *hash function* (Stallings, 2002). For *message encryption,* the original message is encrypted. The encrypted result (or cipher-text) of the entire message serves as its authenticator. To authenticate the content of an image, both the sender and receiver share the same secret key.

Figure 1. Process of digital signature



Message authentication code is a fixed-length value (authenticator) that is generated by a public function with a secret key. The sender and receiver also share the same secret key that is used to generate the authenticator. A *hash function* is a public function that maps a message of any length to a fixed-length hash value that serves as the authenticator. Because there is no secret key adopted in creating an authenticator, the hash functions have to be included in the procedure of digital signature for the electronic exchange of message. The details of how to perform those labeling-based authentication schemes and how to obtain the authentication data are described in the second section.

The non-strict authentication approaches must be chosen when some forms of image modifications (e.g., JPEG lossy compression) are permitted, while malicious manipulation (e.g., objects' deletion and modification) must be detected. This task can be accomplished by extracting features that are invariant to predefined image modifications. Most of the proposed techniques in the literature adopted the same authentication procedure as that performed in digital signature to resolve the legitimacy problem, and exploited invariant features of images to resolve the non-strict authentication. These techniques are often regarded as digital signature-based techniques and will be further discussed in the rest of this chapter. To make the chapter self-contained, some labeling-based techniques that do not follow the standard digital-signature procedures are also introduced in this chapter.

This chapter is organized as follows. Following the introduction in the first section, the second section presents some generic models including strict and non-strict ones for digital signature-based image authentication. This is followed by a section discussing various techniques for image authentication. Next, the chapter addresses the challenges for designing secure digital signature-based image authentication methods. The final section concludes this chapter.

GENERIC MODELS

The digital signature-based image authentication is based on the concept of digital signature, which

is derived from a cryptographic technique called public-key cryptosystem (Diffie & Hellman, 1976; Rivest, Shamir & Adleman, 1978). Figure 1 shows the basic model of digital signature. The sender first uses a hash function, such as MD5 (Rivest, 1992), to hash the content of the original data (or *plaintext*) to a small file (called *digest*). Then the digest is encrypted with the sender's private key. The encrypted digest can form a unique "signature" because only the sender has the knowledge of the private key. The signature is then sent to the receiver along with the original information. The receiver can use the sender's public key to decrypt the signature, and obtain the original digest. Of course, the received information can be hashed by using the same hash function in the sender side. If the decrypted digest matches the newly created digest, the legitimacy and the integrity of the message are therefore authenticated.

There are two points worth noting in the process of digital signature. First, the plaintext is not limited to text file. In fact, any types of digital data, such as digitized audio data, can be the original data. Therefore, the original data in Figure 1 can be replaced with a digital image, and the process of digital signature can then be used to verify the legitimacy and integrity of the image. The concept of trustworthy digital camera (Friedman, 1993) for image authentication is based on this idea. In this chapter, this type of image authentication is referred to as *digital signature-based image authentication*. Second, the hash function is a mathematical digest function. If a single bit of the original image is changed, it may result in a different hash output. Therefore, the strict integrity of the image can be verified, and this is called strict authentication in this chapter. The framework of strict authentication is described in the following subsection.

Strict Authentication

Figure 2 shows the main elements and their interactions in a generic digital signature-based model for image authentication. Assume that the sender wants to send an image I to the receiver, and the legitimate receiver needs to assure the legitimacy and integrity of I. The image I is first hashed to a small file h. Accordingly:

$$h = \mathrm{H}(I), \tag{1}$$

where H(·) denotes hash operator. The hashed result h is then encrypted (signed) with the sender's private key K_R to generate the signature:

$$S = \mathrm{E}_{K_R}(h), \tag{2}$$

where E(·) denotes the public-key encryption operator. The digital signature S is then attached to the original image to form a composite message:

$$M = I \parallel S, \tag{3}$$

where "||" denotes concatenation operator.

If the legitimacy and integrity of the received image I' needs to be verified, the receiver first separates the suspicious image I' from the composite message, and hashes it to obtain the new hashed result, that is:

$$h' = \mathrm{H}(I'). \tag{4}$$

The attached signature is decrypted with the sender's public-key K_p to obtain the possible original hash code:

$$\hat{h} = \mathrm{D}_{Kp}(\hat{S}), \tag{5}$$

where D(·) denotes the public-key decryption operator. Note that we use $\hat{S}$ and $\hat{h}$ respectively to represent the received signature and its hash result because the received signature may be a forged one. The legitimacy and integrity can be confirmed by comparing the newly created hash h' and the possible original hash $\hat{h}$. If they match with each other, we can claim that the received image I' is authentic.

Figure 2. Process of digital signature-based strict authentication

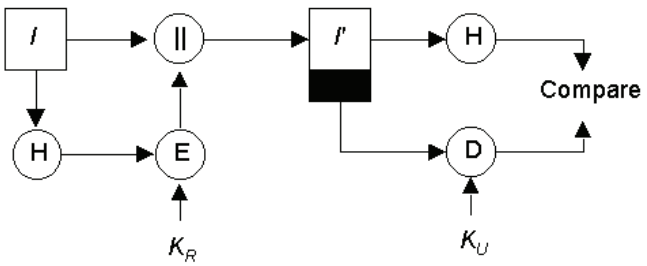


Figure 3. Process of encryption function-based strict authentication

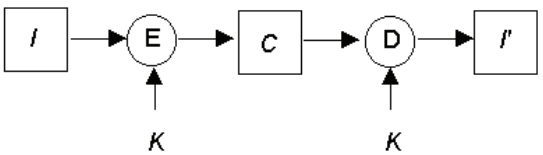
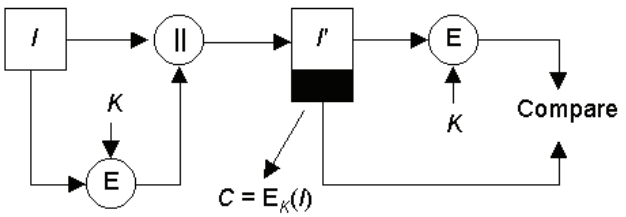


The above framework can be employed to make certain the strict integrity of an image because of the characteristics of the hash functions. In the process of digital signature, one can easily create the hash of an image, but it is difficult to reengineer a hash to obtain the original image. This can be also referred to "*one-way*" property. Therefore, the hash functions used in digital signature are also called *one-way hash* functions. MD5 and SHA (NIST FIPS PUB, 1993) are two good examples of one-way hash functions. Besides one-way hash functions, there are other authentication functions that can be utilized to perform the strict authentication. Those authentication functions can be classified into two broad categories: conventional encryption functions and message authentication code (MAC) functions.

Figure 3 illustrates the basic authentication framework for using conventional encryption functions. An image, *I*, transmitted from the sender to the receiver, is encrypted using a secret key *K* that was shared by both sides. If the decrypted image *I'* is meaningful, then the image is authentic. This is because only the legitimate sender has the shared secret key. Although this is a very straightforward method for strict image authentication, it also provides opponents opportunities to forge a meaningful image. For example, if an opponent has the pair of (*I, C*), he/she can forge an intelligible image *I'* by the *cutting and pasting* method (Li, Lou & Liu, 2003). One solution to this problem is to use the message authentication code (MAC).

Figure 4 demonstrates the basic model of MAC-based strict authentication. The MAC is a cryptographic checksum that is first generated with a shared secret key before the transmission of the original image *I*. The MAC is then transmitted to the receiver along with the original image. In order to assure the integrity, the receiver conducts the same calculation on the received image *I'* using the same secret key to generate a new MAC. If the received MAC matches the calculated MAC, then the integrity of the received image is

Figure 4. Process of MAC-based strict authentication



verified. This is because if an attacker alters the original image without changing the MAC, then the newly calculated MAC will still differ from the received MAC.

The MAC function is similar to the encryption one. One difference is that the MAC algorithm does not need to be reversible. Nevertheless, the decryption formula must be reversible. It results from the mathematical properties of the authentication function. It is less vulnerable to be broken than the encryption function. Although MAC-based strict authentication can detect the fake image created by an attacker, it cannot avoid "legitimate" forgery. This is because both the sender and the receiver share the same secret key. Therefore, the receiver can create a fake image with the shared secret key, and claim that this created image is received from the legitimate sender.

With the existing problems of encryption and MAC functions, the digital signature-based method seems a better way to perform strict authentication. Following the increasing applications that can tolerate one or more content-preserving manipulations, non-strict authentication becomes more and more important nowadays.

Non-Strict Authentication

Figure 5 shows the process of non-strict authentication. As we can see, the procedure of non-strict authentication is similar to that of strict authentication except that the function here used to digest the image is a special-design feature extraction function f_C.

Assume that the sender wants to deliver an image I to the receiver. A feature extraction function f_C is used to extract the image feature and to encode it to a small feature code:

$$C = f_C(I), \tag{6}$$

where $f_C(\cdot)$ denotes feature extraction and coding operator. The extracted feature code has three significant properties. First, the size of extracted feature code is relatively small compared to the size of the original image. Second, it preserves the characteristics of the original image. Third, it can tolerate incidental modifications of the original image. The feature code C is then encrypted (signed) with the sender's private key K_R to generate the signature:

$$S = \mathrm{E}_{K_R}(C). \tag{7}$$

The digital signature S is then attached to the original image to form a composite message:

$$M = I \parallel S. \tag{8}$$

Then the composite message M is forwarded to the receiver. The original image may be lossy compressed, decompressed, or tampered during transmission. Therefore, the received composite message may include a corrupted image I'. The original I may be compressed prior to the concatenation operation. If a lossy compression strategy

is adopted, the original image *I* in the composite message can be considered as a corrupted one.

In order to verify the legitimacy and integrity of the received image *I'*, the receiver first separates the corrupted image *I'* from the composite message, and generates a feature code *C'* by using the same feature extraction function in the sender side, that is:

$$C' = f_C(I'). \quad (9)$$

The attached signature is decrypted with the sender's public-key K_U to obtain the original feature code:

$$\hat{C} = \mathrm{D}_{K_U}(\hat{S}). \quad (10)$$

Note that we use $\hat{S}$ and $\hat{C}$ to represent the received signature and feature code here because the signature may be forged.

The legitimacy and integrity can be verified by comparing the newly generated feature *C'* and the received feature code $\hat{C}$. To differentiate the errors caused by authorized modifications from the errors of malevolent manipulations, let *d*(*C*, *C'*) be the measurement of similarity between the extracted features and the original. Let *T* denote a tolerable threshold value for examining the values of *d*(*C*, *C'*) (e.g., it can be obtained by performing a maximum compression to an image). The received image may be considered authentic if the condition < *T* is met.

Defining a suitable function to generate a feature code that satisfies the requirements for non-strict authentication is another issue. Ideally, employing a feature code should be able to detect content-changing modifications and tolerate content-preserving modifications. The content-changing modifications may include cropping, object addition, deletion, and modification, and so forth, while the content-preserving modifications may include lossy compression, format conversion and contrast *enhancing*, etc.

It is difficult to devise a feature code that is sensitive to all the content-changing modifications, while it remains insensitive to all the content-preserving modifications. A practical approach to design a feature extraction function would be based on the manipulation methods (e.g., JPEG lossy compression). As we will see in the next section, most of the proposed non-strict authentication techniques are based on this idea.

STATE OF THE ART

In this section, several existing digital signature-based image authentication schemes are detailed. Specifically, works related strict authentication is described in the first subsection and non-strict ones in the second subsection. Note that the intention of this section is to describe the methodology of the techniques. Some related problems about these techniques will be further discussed in the fourth section, in which some issues of designing practical schemes of digital signature-based image authentication are also discussed.

Strict Authentication

Friedman (1993) associated the idea of digital signature with digital camera, and proposed a "trustworthy digital camera," which is illustrated as Figure 6. The proposed digital camera uses a digital sensor instead of film, and delivers the image directly in a computer-compatible format. A secure microprocessor is assumed to be built in the digital camera and be programmed with the private key at the factory for the encryption of the digital signature. The public key necessary for later authentication appears on the camera body as well as the image's border. Once the digital camera captures the objective image, it produces two output files. One is an all-digital industry-standard file format representing the captured image; the other is an encrypted digital signature generated by applying the camera's unique private key (embedded in the camera's secure microprocessor) to a hash of the captured image

Figure 6. Idea of the trustworthy digital camera

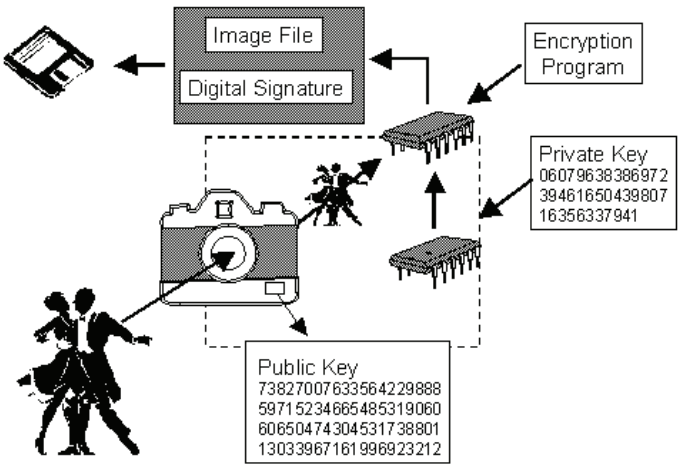


Figure 7. Verification process of Friedman's idea

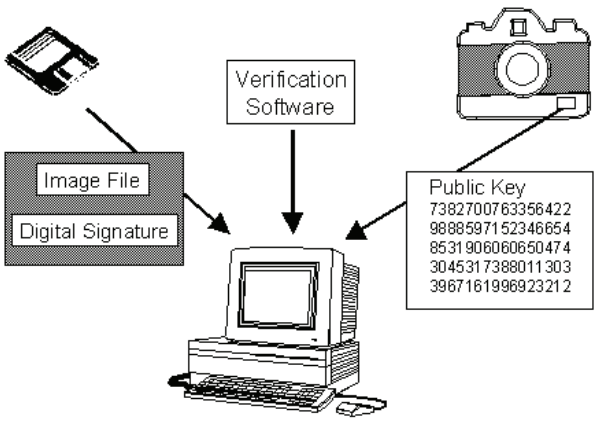

file, a procedure described in the second section. The digital image file and the digital signature can later be distributed freely and safely.

The verification process of Friedman's idea is illustrated in Figure 7. The image authentication can be accomplished with the assistance of the public domain verification software. To authenticate a digital image file, the digital image, its accompanying digital signature file, and the public key are needed by the verification software running on a standard computer platform. The program then calculates the hash of the input image, and uses the public key to decode the digital signature to reveal the original hash. If these two hash values match, the image is considered to be authentic. If these two hash values are different, the integrity of this image is questionable.

It should be noted that the hash values produced by using the cryptographic algorithm such as MD5 will not match if a single bit of the image file is changed. This is the characteristic of the strict authentication, but it may not be suitable for authenticating images that undergo lossy compression. In this case, the strict authentication code (hash values) should be generated in a non-strict way. Non-strict authentication schemes have been proposed for developing such algorithms.

Non-Strict Authentication

Instead of using a strict authentication code, Schneider and Chang (1996) used content-based data as the authentication code. Specifically, the content-based data can be considered to be the image feature. As the image feature is invariant for some content-preserving transformation, the original image can also be authenticated although it may be manipulated by some allowable image transformations. The edge information, DCT coefficients, color, and intensity histograms are regarded as potentially invariant features. In Schneider and Chang's method, the intensity histogram is employed as the invariant feature in the implementation of the content-based image authentication scheme. To be effective, the image is divided into blocks of variable sizes and the intensity histogram of each block is computed separately and is used as the authentication code.

To tolerate incidental modifications, the Euclidean distance between intensity histograms was used as a measure of the content of the image. It is reported that the lossy compression ratio that could be applied to the image without producing a false positive is limited to 4:1 at most. Schneider and Chang also pointed out that using a reduced distance function can increase the maximum permissible compression ratio. It is found that the alarm was not triggered even at a high compression ratio up to 14:1 if the block average intensity is used for detecting image content manipulation. Several works have been proposed in the literature based on this idea. They will be introduced in the rest of this subsection.

Feature-Based Methods

The major purpose of using the image digest (hash values) as the signature is to speed up the signing procedure. It will violate the principle of the digital signature if large-size image features were adopted in the authentication scheme. Bhattacharjee and Kutter (1998) proposed another algorithm to extract a smaller size feature of an image. Their feature extraction algorithm is based on the so-called *scale interaction model*. Instead of using Gabor wavelets, they adopted Mexican-Hat wavelets as the filter for detecting the feature points. The algorithm for detecting feature-points is depicted as follows.

- Define the feature-detection function, $P_{ij}(\cdot)$ as:

$$P_{ij}(\vec{x}) = | M_i(\vec{x}) - \gamma \cdot M_j(\vec{x}) | \qquad (11)$$

  where $M_i(\vec{x})$ and $M_j(\vec{x})$ represent the responses of Mexican-Hat wavelets at the image-location $\vec{x}$ for scales *i* and *j*, respectively. For the image *A*, the wavelet response $M_i(\vec{x})$ is given by:

$$M_i(\vec{x}) = \langle (2^{-i}\psi(2^{-i} \cdot \vec{x})); A \rangle \qquad (12)$$

  where <;> denotes the convolution of its operands. The normalizing constant γ is given by $\gamma = 2^{-(i-j)}$, the operator $|\cdot|$ returns the absolute value of its parameter, and the $\psi(\vec{x})$ represents the response of the Mexican-Hat mother wavelet, and is defined as:

$$\psi(\vec{x}) = (2 - |\vec{x}|^2) \exp(-\frac{\vec{x}^2}{2}) \qquad (13)$$

- Determine points of local maximum of $P_{ij}(\cdot)$. These points correspond to the set of potential feature points.

- Accept a point of local maximum in $P_{ij}(\cdot)$ as a feature-point if the variance of the image-pixels in the neighborhood of the point is higher than a threshold. This criterion eliminates suspicious local maximum in featureless regions of the image.

The column-positions and row-positions of the resulting feature points are concatenated to form a string of digits, and then encrypted to generate the image signature. It is not hard to imagine that the file constructed in this way can have a smaller size compared to that constructed by recording the block histogram.

In order to determine whether an image *A* is authentic with another known image *B*, the feature set S_A of *A* is computed. The feature set S_A is then compared with the feature set S_B of *B* that is decrypted from the signature of *B*. The following rules are adopted to authenticate the image *A*.

- Verify that each feature location is present both in S_B and in S_A.
- Verify that no feature location is present in S_A but absent in S_B.
- Two feature points with coordinates and are said to match if:

$$|\vec{x} - \vec{y}| < 2 \qquad (14)$$

Edge-Based Methods

The edges in an image are the boundaries or contours where the significant changes occur in some physical aspects of an image, such as the surface reflectance, illumination, or the distances of the visible surfaces from the viewer. Edges are kinds of strong content features for an image. However, for common picture formats, coding edges value and position produces a huge overhead. One way to resolve this problem is to use a binary map to represent the edge. For example, Li, Lou and Liu (2003) used a binary map to encode the edges of an image in their watermarking-based image authentication scheme. It should be concerned that edges (both their position and value, and also the resulting binary image) might be modified if high compression ratios are used. Consequently, the success of using edges as the authentication code is greatly dependent on the capacity of the authentication system to discriminate the differences the edges produced by content-preserving manipulations from those content-changing manipulations. Queluz (2001) proposed an algorithm for edges extraction and edges integrity evaluation.

The block diagram of the edge extraction process of Queluz's method is shown as Figure 8. The gradient is first computed at each pixel position with an edge extraction operator. The result is then compared with an image-dependent threshold obtained from the image gradient histogram to obtain a binary image marking edge and no-edge pixels. Depending on the specifications for label size, the bit-map could be sub-sampled with the purpose of reducing its spatial resolution. Finally, the edges of the bit-map are encoded (compressed).

Edges integrity evaluation process is shown as Figure 9. In the *edges difference computation* block, the suspicious error pixels that have differences between the original and computed edge bit-maps and a certitude value associated with each error pixel are produced. These suspicious error pixels are evaluated in an *error relaxation* block. This is done by iteratively changing low certitude errors to high certitude errors if necessary, until no further change occurs. At the end, all high certitude errors are considered to be true errors and low certitude errors are eliminated. After error relaxation, the maximum connected region is computed according to a predefined threshold.

A similar idea was also proposed by Dittmann, Steinmetz and Steinmetz (1999). The feature-extraction process starts with extracting the edge characteristics C_I of the image *I* with the Canny edge detector *E* (Canny, 1986). The

Figure 8. Process of edge extraction proposed by Queluz (2001)

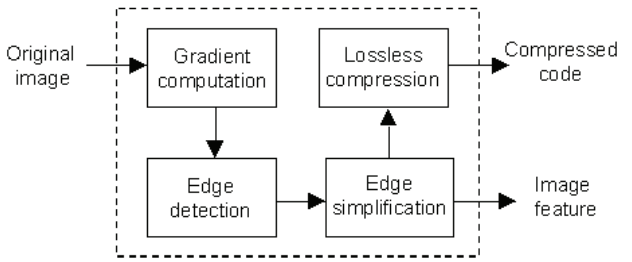

Figure 9. Process of edges integrity evaluation proposed by Queluz (2001)

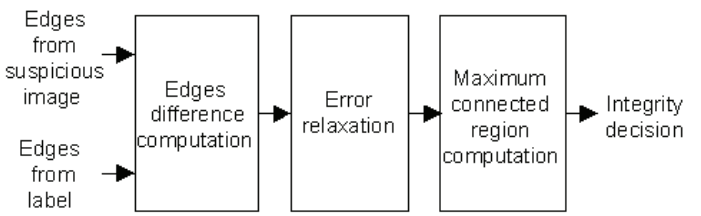

C_I is then transformed to a binary edge pattern EP_{CI}. The variable length coding is then used to compress EP_{CI} into a feature code. This process is formulated as follows:

- Feature extraction: $C_I = E(I)$;
- Binary edge pattern: $EP_{CI} = f(C_I)$;
- Feature code: $VLC(EP_{CI})$.

The verification process begins with calculating the actual image edge characteristic C_T and the binary edge pattern EP_{CT}. The original binary edge pattern EP_{CI} is obtained by decompressing the received $VLC(EP_{CI})$. The EP_{CI} and CP_{CT} are then compared to obtain the error map. These steps can also be formulated as follows:

- Extract feature: $C_T = E(T)$, $EP_{CT} = f(C_T)$;
- Extract the original binary pattern: EP_{CI} = Decompress($VLC(EP_{CI})$);
- Check $EP_{CI} = EP_{CT}$.

Mean-Based Methods

Using local mean as the image feature may be the simplest and most practical way to represent the content character of an image. For example, Lou and Liu (2000) proposed an algorithm to generate a mean-based feature code. Figure 10 shows the process of feature code generation. The original image is first divided into non-overlapping blocks. The mean of each block is then calculated and quantized according to a predefined parameter. All the calculated results are then encoded (compressed) to form the authentication code. Figure 11 shows an example of this process. Figure 11(a) is a 256×256 gray image, and is used as the original image. It is first divided into 8×8 non-overlapping blocks. The mean of each block is then computed and is shown as Figure 11(b). Figure 11(c) also

shows the 16-step quantized block-means of Figure 11(b). The quantized block-means are further encoded to form the authentication code. It should be noted that Figure 11(c) is visually close to Figure 11(b). It means that the feature of the image is still preserved even though only the quantized block-means are encoded.

The verification process starts with calculating the quantized block-means of the received image. The quantized code is then compared with the original quantized code by using a sophisticated comparison algorithm. A binary error map is then produced as an output, with "1" denoting *match* and "0" denoting *mismatch*. The verifier can thus tell the possibly tampered blocks by inspecting the error map. It is worth mentioning that the quantized block-means can be used to repair the tampered blocks. This feasibility is attractive in the applications of the real-time image such as the video.

A similar idea was adopted in the process of generating the AIMAC (Approximate Image Message Authentication Codes) (Xie, Arce & Graveman, 2001). In order to construct a robust IMAC, an image is divided into non-overlapping 8×8 blocks, and the block mean of each block is computed. Then the most significant bit (MSB) of each block mean is extracted to form a binary map. The AIMAC is then generated according to this binary map. It should be noted that the histogram of the pixels in each block should be adjusted to preserve a gap of 127 gray levels for each block mean. In such a way, the MSB is robust enough to distinguish content-preserving manipulations from content-changing manipulations. This part has a similar effectiveness to the sophisticated comparison part of the algorithm proposed by Lou and Liu (2000).

Relation-Based Methods

Unlike the methods introduced above, relation-based methods divide the original image into non-overlapping blocks, and use the relation between blocks as the feature code. The method proposed by Lin and Chang (1998, 2001) is called SARI. The feature code in SARI is generated to survive the JPEG compression. To serve this purpose, the process of the feature code generation starts with dividing the original image into 8×8 non-overlapping blocks. Each block is then DCT transformed. The transformed DCT blocks are further grouped into two non-overlapping sets. There are equal numbers of DCT blocks in each set (i.e., there are $N/2$ DCT blocks in each set if the original image is divided into N blocks). A secret key-dependent mapping function then one-to-one maps each DCT block in one set into another DCT block in the other set, and generates $N/2$ DCT block pairs. For each block pair, a number of DCT coefficients are then selected and compared. The feature code is then generated by comparing the corresponding coefficients of the paired blocks. For example, if the coefficient in the first DCT block is greater than the coefficient in the second DCT block, then code is generated as "1". Otherwise, a "0" is generated. The process of generating the feature code is illustrated as Figure 12.

To extract the feature code of the received image, the same secret key should be applied in the verification process. The extracted feature code

Figure 10. Process of generation of image feature proposed by Lou and Liu (2000)

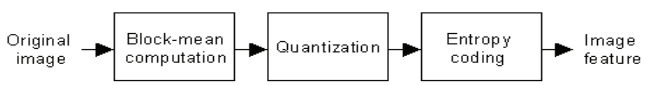

Figure 11. (a) Original image, (b) Map of block-means, (c) Map of 16-step quantized block-means

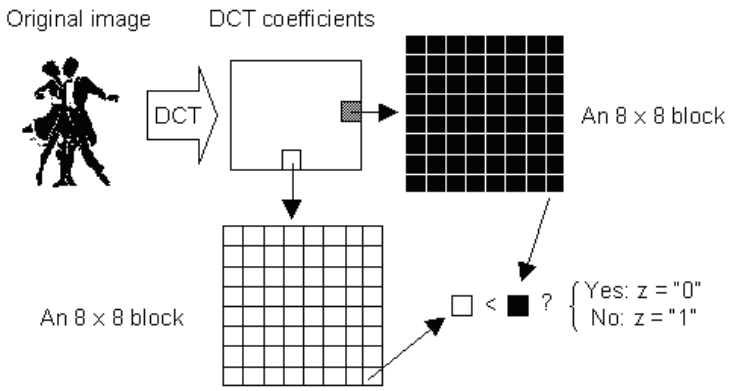
Figure 12. Feature code generated with SARI authentication scheme



is then compared with the original feature code. If either block in each block pair has not been maliciously manipulated, the relation between the selected coefficients is maintained. Otherwise, the relation between the selected coefficients may be changed.

It can be proven that the relationship between the selected DCT coefficients of two given image blocks is maintained even after the JPEG compression by using the same quantization matrix for the whole image. Consequently, SARI authentication system can distinguish JPEG compression from other malicious manipulations. Moreover, SARI can locate the tampered blocks because it is a block-wise method.

Structure-Based Methods

Lu and Liao (2000, 2003) proposed another kind of method to generate the feature code. The feature code is generated according to the structure of the image content. More specifically, the content structure of an image is composed of parent-child pairs in the wavelet domain. Let $w_{s,o}(x, y)$ be a wavelet coefficient at the scale s. Orientation o denotes horizontal, vertical, or diagonal direction. The inter-scale relationship of wavelet coefficients is defined for the parent node $w_{s+1,o}(x, y)$ and its four children nodes $w_{s,o}(2x+i, 2y+j)$ as either $|w_{s+1,o}(x, y)| \geq |w_{s,o}(2x+i, 2y+j)|$ or $|w_{s+1,o}(x, y)| \leq |w_{s,o}(2x+i, 2y+j)|$, where $0 \leq i, j \leq 1$.

The authentication code is generated by recording the parent-child pair that satisfies $\|w_{s+1,o}(x, y)| - |w_{s,o}(2x+i, 2y+j)\| > \rho$, where $\rho > 0$. Clearly, the threshold ρ is used to determine the size of the authentication code, and plays a trade-off role between robustness and fragility. It is proven that the inter-scale relationship is difficult to be destroyed by content-preserving manipulations and is hard to be preserved by content-changing manipulations.

DESIGN ISSUES

Digital signature-based image authentication is an important element in the applications of image communication. Usually, the content verifiers are not the creator or the sender of the original image. That means the original image is not available during the authentication process. Therefore, one of the fundamental requirements for digital signature-based image authentication schemes is *blind authentication*, or *obliviousness*, as it is sometimes called. Other requirements depend on the applications that may be based on strict authentication or non-strict authentication. In this section, we will discuss some issues about designing effective digital signature-based image authentication schemes.

Error Detection

In some applications, it is proper if modification of an image can be detected by authentication schemes. However, it is beneficial if the authentication schemes are able to detect or estimate the errors so that the distortion can be compensated or even corrected. Techniques for error detection can be categorized into two classes according to the applications of image authentication; namely, error type and error location.

Error Type

Generally, strict authentication schemes can only determine whether the content of the original image is modified. This also means that they are not able to differentiate the types of distortion (e.g., compression or filtering). By contrast, non-strict authentication schemes tend to tolerate some form of errors. The key to developing a non-strict authentication scheme is to examine what the digital signature should protect. Ideally, the authentication code should protect the message conveyed by the content of the image, but not the particular representation of that content of the image. Therefore, the authentication code can be used to verify the authenticity of an image that has been incidentally modified, leaving the value and meaning of its contents unaffected. Ideally, one can define an authenticity versus modification curve such as the method proposed by Schneider and Chang (1996) to achieve the desired authenticity. Based on the authenticity versus modification curve, authentication is no longer a yes-or-no question. Instead, it is a continuous interpretation. An image that is bit by bit identical to the original image has an authenticity measure of 1.0 and is considered to be completely authentic. An image that has nothing in common with the original image has an authenticity measure of 0.0 and is considered unauthentic. Each of the other images would have authenticity measure between the range (0.0, 1.0) and be partially authentic.

Error Location

Another desirable requirement for error detection in most applications is errors localization. This can be achieved by block-oriented approaches. Before transmission, an image is usually partitioned into blocks. The authentication code of each block is calculated (either for strict or non-strict authentication). The authentication codes of the original image are concatenated, signed, and transmitted as a separate file. To locate the

distorted regions during the authenticating process, the received image is partitioned into blocks first. The authentication code of each block is calculated and compared with the authentication code recovered from the received digital signature. Therefore, the smaller the block size is, the better the localization accuracy is. However, the higher accuracy is gained at the expense of the larger authentication code file and the longer process of signing and decoding. The trade-off needs to be taken into account at the designing stage of an authentication scheme.

Error Correction

The purpose of error correction is to recover the original images from their manipulated version. This requirement is essential in the applications of military intelligence and motion pictures (Dittmann, Steinmetz & Steinmetz, 1999; Queluz, 2001). Error correction can be achieved by means of error correction code (ECC) (Lin & Costello, 1983). However, encrypting ECC along with feature code may result in a lengthy signature. Therefore, it is more advantageous to enable the authentication code itself to be the power of error correction. Unfortunately, the authentication code generated by strict authentication schemes is meaningless and cannot be used to correct the errors. Compared to strict authentication, the authentication code generated by non-strict authentication schemes is potentially capable of error correction. This is because the authentication code generated by the non-strict authentication is usually derived from the image feature and is highly content dependent.

An example of using authentication code for image error correction can be found in Xie, Arce and Graveman (2001). This work uses quantized image gray values as authentication code. The authenticated code is potentially capable of error correcting since image features are usually closely related to image gray values. It should be noted that the smaller the quantization step is, the better the performance of error correction is. However, a smaller quantization step also means a longer signature. Therefore, trade-off between the performance of error correction and the length of signature has to be made as well. This is, without doubt, an acute challenge, and worth further researching.

Security

With the protection of public-key encryption, the security of the digital signature-based image authentication is reduced to the security of the image digest function that is used to produce the authentication code. For strict authentication, the attacks on hash functions can be grouped into two categories: brute-force attacks and cryptanalysis attacks.

Brute-Force Attacks

It is believed that, for a general-purpose secure hash code, the strength of a hash function against brute-force attacks depends solely on the length of the hash code produced by the algorithm. For a code of length n, the level of effort required is proportional to $2^{n/2}$. This is also known as *birthday attack*. For example, the length of the hash code of MD5 (Rivest, 1992) is 128 bits. If an attacker has 2^{64} different samples, he or she has more than 50% of chances to find the same hash code. In other words, to create a fake image that has the same hash result as the original image, an attacker only needs to prepare 2^{64} visually equivalent fake images. This can be accomplished by first creating a fake image and then varying the least significant bit of each of 64 arbitrarily chosen pixels of the fake image. It has been proved that we could find a collision in 24 days by using a $10 million collision search machine for MD5 (Stallings, 2002). A simple solution to this problem is to use a hash function to produce a longer hash code. For example, SHA-1 (NIST FIPS PUB 180, 1993) and RIPEMD-160 (Stall-

ings, 2002) can provide 160-bit hash code. It is believed that over 4,000 years would be required if we used the same search machine to find a collision (Oorschot & Wiener, 1994). Another way to resolve this problem is to link the authentication code with the image feature such as the strategy adopted by non-strict authentication.

Non-strict authentication employs image feature as the image digest. This makes it harder to create enough visually equivalent fake images to forge a legal one. It should be noted that, mathematically, the relationship between the original image and the authentication code is many-to-one mapping. To serve the purpose of error tolerance, non-strict authentication schemes may have one authentication code corresponding to more images. This phenomenon makes non-strict authentication approaches vulnerable and remains as a serious design issue.

Cryptanalysis Attacks

Cryptanalysis attacks on digest function seek to exploit some property of the algorithm to perform some attack rather than an exhaustive search. Cryptanalysis on the strict authentication scheme is to exploit the internal structure of the hash function. Therefore, we have to select a secure hash function that can resist cryptanalysis performed by attackers. Fortunately, so far, SHA-1 and RIPEMD-160 are still secure for various cryptanalyses and can be included in strict authentication schemes. Cryptanalysis on non-strict authentication has not been defined so far. It may refer to the analysis of key-dependent digital signature-based schemes. In this case, an attacker tries to derive the secret key from multiple feature codes, which is performed in a SARI image authentication system (Radhakrisnan & Memon, 2001). As defined in the second section, there is no secret key involved in a digital signature-based authentication scheme. This means that the secrecy of the digital signature-based authentication schemes depends on the robustness of the algorithm itself and needs to be noted for designing a secure authentication scheme.

CONCLUSION

With the advantages of the digital signature (Agnew, Mullin & Vanstone, 1990; ElGamal, 1985; Harn, 1994; ISO/IEC 9796, 1991; NIST FIPS PUB, 1993; Nyberg & Rueppel, 1994; Yen & Laih, 1995), digital signature-based schemes are more applicable than any other schemes in image authentication. Depending on applications, digital signature-based authentication schemes are divided into strict and non-strict categories and are described in great detail in this chapter. For strict authentication, the authentication code derived from the calculation of traditional hash function is sufficiently short. This property enables fast creation of the digital signature. In another aspect, the arithmetic-calculated hash is very sensitive to the modification of image content. Some tiny changes to a single bit in an image may result in a different hash. This results in that strict authentication can provide binary authentication (i.e., yes or no). The trustworthy camera is a typical example of this type of authentication scheme.

For some image authentication applications, the authentication code should be sensitive for content-changing modification and can tolerate some content-preserving modification. In this case, the authentication code is asked to satisfy some basic requirements. Those requirements include locating modification regions and tolerating some forms of image processing operations (e.g., JPEG lossy compression). Many non-strict authentication techniques are also described in this chapter. Most of them are designed to employ a special-purpose authentication code to satisfy those basic requirements shown above. However, few of them are capable of recovering some certain errors. This special-purpose authentication code may be the modern and useful aspect for non-strict authentication.

Under the quick evolution of image processing techniques, existing digital signature-based image authentication schemes will be further improved to meet new requirements. New requirements pose new challenges for designing effective digital signature-based authentication schemes. These challenges may include using large-size authentication code and tolerating more image-processing operations without compromising security. This means that new approaches have to balance the trade-off among these requirements. Moreover, more modern techniques combining the watermark and digital signature techniques may be proposed for new image authentication generations. Those new image authentication techniques may result in some changes of the watermark and digital signature framework, as demonstrated in Sun and Chang (2002), Sun, Chang, Maeno and Suto (2002a, 2002b) and Lou and Sung (to appear).

Chapter 7.11
A Stochastic Content-Based Image Retrieval Mechanism

ABSTRACT

Multimedia information, typically image information, is growing rapidly across the Internet and elsewhere. To keep pace with the increasing volumes of image information, new techniques need to be investigated to retrieve images intelligently and efficiently. Content-based image retrieval (CBIR) is always a challenging task. In this chapter, a stochastic mechanism, called Markov Model Mediator (MMM), is used to facilitate the searching and retrieval process for content-based image retrieval, which serves as the retrieval engine of the CBIR systems and uses stochastic-based similarity measures. Different from the common methods, our stochastic mechanism carries out the searching and similarity computing process dynamically, taking into consideration not only the image content features but also other characteristics of images such as their access frequencies and access patterns. Our experimental results demonstrate that the MMM mechanism together with the stochastic process can assist in retrieving more accurate results for user queries.

INTRODUCTION

The availability of today's digital devices and techniques offers people more opportunities than ever to create their own digital images. Moreover, the Internet has become the biggest platform to get, distribute and exchange digital image data. The rapid increase in the amount of image data and the inefficiency of traditional text-based image retrieval have created great demands for new approaches in image retrieval. As a consequence

of such fast growth of digital image databases, the development of efficient search mechanisms has become more and more important. Content-Based Image Retrieval (CBIR) emerges and is dedicated to tackling such difficulties. CBIR is an active research area where the image retrieval queries are based on the content of multimedia data.

In contrast to the text-based approach, CBIR operates on a totally different principle, i.e., to retrieve the stored images from a collection of images by comparing the features that were automatically extracted from the images themselves. Content-based image retrieval involves a matching process between a query image and the images stored in the database. The first step of the process involves extracting a feature vector for the unique characteristics of each image. The features used for retrieval can be either primitive or semantic, but the extraction process must be automatic. A quantified similarity value between two images is obtained by comparing their feature vectors. The commonly used image features include color, shape and texture. Queries are issued through query by image example (QBE), which can either be provided or constructed by users, or randomly selected from the image database. A lot of research work has been done, which resulted in a number of systems and techniques, both in the academic and commercial domains. For example, IBM's QBIC system (Faloutsos, 1994; Flickner, 1995) and Virage's VIR engine (*http://www.virage.com*) are two of the most notable commercial image retrieval systems, while VisualSEEk (Smith, 1996) and PhotoBook (Pentland, 1994) are well-known academic image retrieval systems.

For large image collections, traditional retrieval methods such as sequential searching do not work well since it is time expensive and tends to ignore the relationships among all images by only considering the relationship between the query image and a single image in the database. Various kinds of data structures, approaches and techniques have been proposed to manage image databases and hasten the retrieval process.

The first aim of this chapter is to take an overview of the currently available content-based image retrieval (CBIR) systems. Then, with the focus on the searching process, we present a conceptually coherent framework that adopts a stochastic mechanism called Markov Model Mediator (MMM) for the content-based image retrieval problem. With an explicit model of image query patterns, given the target image, the proposed framework carries out the searching and similarity computing process dynamically by taking into consideration not only the image content features but also their access frequencies and access patterns.

We begin with the literature review as well as the motivations of the proposed mechanism. Then, the key components of the MMM mechanism and the stochastic process for information retrieval are introduced. After that, our experiments in applying the MMM mechanism to content-based image retrieval are presented and the experimental results are also provided. The future trends are discussed as well. Finally, a brief conclusion is given.

BACKGROUND

The objective of a CBIR system is to offer the user an efficient way in finding and retrieving those images that are qualified for the matching criteria of the users' queries from the database. Most of the existing CBIR systems retrieve images in the following manner. First, they build the indexes based on the low-level features such as color, texture and shape for the images in the database. The corresponding indexes of a query image are also generated at the time the query is issued. Second, they search through the whole database and measure the similarity of each image to the query image. Finally, the results are returned in a sorted order of the similarity matching level.

Lots of approaches for retrieving images on the basis of color similarity have been described

in the literature, but most of them are actually variations of the same basic idea. The most commonly used matching technique is histogram intersection (Li, 2000). Variants of this technique are now used in a big proportion of the current CBIR systems. Methods of improving the original technique include the use of cumulative color histograms, combining histogram intersection with some element of spatial matching (Stricker, 1996) and the use of region-based color querying (Carson, 1997). As for texture similarity, the useful measures include the degree of *contrast*, *coarseness*, *directionality*, *regularity*, *periodicity*, *randomness*, etc. Alternative methods of texture analysis for retrieval include the use of Gabor filters (Ma, 1998) and fractals (Kaplan, 1998). Unlike texture, shape is a fairly well defined concept. Two main types of shape features are commonly used, namely (1) the *global* features such as aspect ratio, circularity and moment invariants and (2) the *local* features such as sets of consecutive boundary segments. Alternative methods proposed for shape matching include elastic deformation of templates (Zhong, 2000).

An impediment to research on CBIR is the lack of mapping between the high-level concepts and the low-level features. In order to overcome this problem and to better capture the subjectivity of human perception of the visual content, the concept of relevance feedback (RF) associated with CBIR was proposed in Rui (1997). Relevance feedback is an interactive process in which the user judges the quality of the retrieval results performed by the system by marking those images that the user perceives as truly relevant among the images retrieved by the system. This information is then used to refine the original query. However, even if the user provides a good initial query, it is still a problem of how to navigate through the image database.

No matter what information and what techniques are used for the construction of the image indexes, and no matter what similarity measurement strategies are employed, as far as the searching process is concerned, simple approaches such as sequential searching, are commonly put into operations to find the group of similar images for the queries. Such kinds of approaches may be adequate for small databases. However, as the scales and volumes of the databases increase considerably, they are deficient. Moreover, these approaches focus on only the relationship between the query image and the target image, neglecting the relationships among all the images within the database, which may result in inflexible and incomplete searching results.

There have been quite a few techniques being proposed and employed to alleviate the time consumption problem and to speed up the retrieval process, such as efficient indexing structures, compact representations, and pre-filtering techniques (Hafner, 1995). The QBIC system (Faloutsos, 1994; Flickner, 1995), for instance, uses the pre-filtering technique and the efficient indexing structure like R-trees to accelerate its searching performance. However, little has been done in considering the complicated relationships of the image objects to each other.

In this chapter, we present a content-based retrieval system that employs the Markov model mediator (MMM) mechanism to retrieve images, which functions as both the searching engine and image similarity arbitrator. In our previous studies, the MMM mechanism has been applied to multimedia database management (Shyu, 2000a, 2000c) and document management on the World Wide Web (WWW) (Shyu, 2000b, 2001a, 2001b). The MMM mechanism adopts the Markov model framework and the concept of the mediators. The Markov model is one of the most powerful tools available to scientists and engineers for analyzing complicated systems, whereas a mediator is defined as a program that collects and combines information from one or more sources, and finally yields the resulting information (Wiederhold, 1992). A Markov model consists of a number of states connected by transitions. The Markov property states that given the current state of the

system, the future evolution is independent of its history. In other words, the states represent the alternatives of the stochastic process and the transitions contain probabilistic and other data used to determine which state should be selected next. All the transitions $S_i \rightarrow S_j$ such that $Pr(S_j \mid S_i) > 0$ are said to be allowed, the rest are prohibited. Markov models have been used in many applications. Some well-known examples are Markov Random Field Models in Frank (1986), and Hidden Markov Models (HMMs) (Rabiner, 1986). Some research works have been done to integrate the Markov model into the field of image retrieval. Lin et al. (Lin, 1997) used a Markov model to combine the spatial and color information. In their approach, each image in the database is represented by a pseudo two-dimensional hidden Markov model (HMM) in order to adequately capture both the spatial and chromatic information about that image. Wolf (1997) used the hidden Markov model (HMM) to parse video data. In Naphade (2001), the hidden Markov model was employed to model the time series of the feature vector for the cases of events and objects in their probabilistic framework for semantic level indexing and retrieval.

Our proposed CBIR system employs the MMM mechanism as well as the stochastic-based similarity measures for dynamic content-based image retrieval, which retrieves images with respect to the user queries. Our method also builds an index vector for each image within the database, but unlike the common methods mentioned above, our method considers not only the relationship between the query image and the target image, but also the relationships among all images in the database. A stochastic process that takes into account the image content features and other characteristics (such as the access frequencies and access patterns) of the images is proposed. Several experiments are conducted and the experimental results demonstrate that the MMM mechanism together with the stochastic process can assist in retrieving more accurate results for user queries.

THE STOCHASTIC MODEL

Markov Model Mediator (MMM) Mechanism

Markov model mediator (MMM) is a probabilistic-based mechanism that adopts the Markov model framework and the mediator concept (Shyu, 2000a, 2000b, 2000c, 2001a, 2001b). In our CBIR system, each image database is modeled by an MMM. The MMM mechanism is defined as follows.

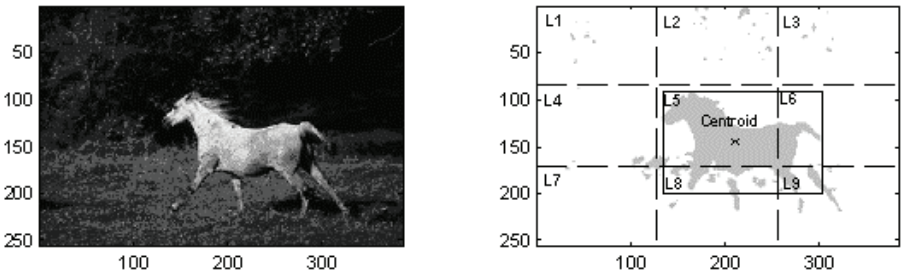
Definition 1: An MMM is represented by a 5-tuple $\lambda = (\mathcal{S}, \mathcal{F}, \mathcal{A}, \mathcal{B}, \Pi)$*, where* $\mathcal{S}$ *is a set of images called states;* $\mathcal{F}$ *is a set of distinct features of the images;* $\mathcal{A}$ *denotes the state transition probability distribution, where each entry (i, j) actually indicates the relationship between images i and j;* $\mathcal{B}$ *is the observation symbol probability distribution; and* Π *is the initial state probability distribution.*

Each image database is modeled by an MMM, where $\mathcal{S}$ consists of all the images in the image database and $\mathcal{F}$ includes all the distinct features for the images in $\mathcal{S}$. The elements in $\mathcal{S}$ and $\mathcal{F}$ determine the dimensions of $\mathcal{A}$ and $\mathcal{B}$. If there are totally n images in $\mathcal{S}$, and the number of distinct features in $\mathcal{F}$ is m, then the dimensions of $\mathcal{A}$ is $n \times n$, while $\mathcal{B}$ has the size of $n \times m$. The relationships of the images are modeled by the sequences of the MMM states connected by transitions. A training data set consisting of the access patterns and access frequencies of the queries issued to the database is used to train the model parameters for an MMM.

Formulation of the Model Parameters

Each MMM has three probability distribution matrixes: $\mathcal{A}$, $\mathcal{B}$, and Π. These matrixes are criti-

Figure 1. Object locations and their corresponding regions



cal for the stochastic process and can be obtained from the training data set.

Matrix B: The Observation Symbol Probability Distribution

The observation symbol probability $\mathcal{B}$ denotes the probability of observing an output symbol from a state. Here, the observed output symbols represent the distinct features of the images and the states represent the images in the database. Since an image has one or more features and one feature can appear in multiple images, the observation symbol probabilities show the probabilities that a feature is observed from a set of images.

In this study, we consider the following features: color information and object location information for the images in the image database. Since the color feature is closely associated with image scenes and it is more robust to changes due to scaling, orientation, perspective and occlusion of images, it is the most widely used visual feature in image retrieval (Ma, 1999). Humans perceive a color as a combination of three stimuli, R (red), G (Green), and B (Blue), which form a color space. Separating chromatic information and luminance information can generate more color spaces such as RGB, YIQ, YUV, CIE LAB, CIE LUV, and HSV. None of them can be used for all applications (Androutsos, 1999; Aslandogan, 1999; Cheng, 2001, 2000; Ma, 1999; Rui, 1999). RGB is the most commonly used color space primarily because color image acquisition and recording hardware are designed for this space. However, the problem of this space is the close correlation among the three components, which means that all three components will change as the intensity changes. This is not good for color analysis. YIQ and YUV are used to represent the color information in TV signals in color television broadcasting. CIE LAB and CIE LUV are often used in measuring the distance between two colors because of their perceptual uniformity. However, its transformation from the RGB space is computationally intensive and dependent on a reference white.

In our CBIR system, color information is obtained for each image from its HSV color space. The whole color space is divided into 12 subspaces according to the combinations of different ranges of hue (H), saturation (S), and intensity values (V). The HSV color space is chosen for two reasons. First, it is perceptual, which makes HSV a proven color space particularly amenable to color image analysis (Androutsos, 1999; Cheng, 2001, 2000). Secondly, the benchmark results in Ma (1999) shows that the color histogram in the HSV color space performs the best. For information of object locations, the SPCPE algorithm proposed in Sista (1999) and Chen (2000) is used.

img3	0.26	0	0	0.15	0	0	0.09	0	0	0	0	0	0	0	0	0	0.5	0	0	0	0

The minimal bounding rectangle (MBR) concept in R-tree (Guttman, 1984) is adopted so that each object is covered by a rectangle. The centroid point of each object is used for space reasoning so that any object is mapped to a point object. When these features are integrated into the queries, the semantic level meaning in the users' queries can be captured.

In our experiments, each image has a feature vector of 21 elements. Within the 21 features, 12 are for color descriptions and nine are for location descriptions. The color features considered are 'black,' 'white' (w), 'red,' 'red-yellow' (ry), 'yellow' (y), 'yellow-green' (yg), 'green,' 'green-blue' (gb), 'blue' (b), 'blue-purple' (bp), 'purple' (p), and 'purple-red' (pr). Colors with a number of pixels less than 5% of the total number of pixels are regarded as non-important and the corresponding positions in the feature vector have a value of 0. Otherwise, we put the corresponding percentage of that color component to that position. As for the location descriptions, each image is divided into 3×3 equal-sized regions. The image can be divided into a coarser or finer set of regions if necessary. As shown in Figure 1, the nine regions are ordered from left to right and top to bottom: L1, L2, L3, L4, L5, L6, L7, L8, and L9. When there is an object in the image whose centroid falls into one of the nine regions, the value 1 is assigned to that region. Objects with their areas less than 8% of the total area are ignored.

In order to capture the appearance of a feature in an image, we define a temporary matrix ($\mathcal{BB}$) whose rows are all the distinct images and columns are all the distinct features, where the value in the $(p, q)^{th}$ entry is greater than zero if feature

q appears in image p, and 0 otherwise. Then, the observation symbol probability distribution $\mathcal{B}$ can be obtained via normalizing $\mathcal{BB}$ per row. In other words, the sum of the probabilities that the features are observed from a given image should be 1.

Matrix $\mathcal{BB}$ consists of image feature vectors for all images. Figure 2 gives three example images and Table 1 illustrates their associated feature vectors. The observation symbol probability distribution $\mathcal{B}$ can be obtained via normalizing $\mathcal{BB}$ per row as shown in Table 2. In other words, the sum of the probabilities that the features are observed from a given image should be 1. We consider that the color and location information are of equal importance, such that the sum of observed probability of color features should be equal to that of location features (0.5 each).

Training Data Set

A set of training data is used to generate the training traces that are the central part of the stochastic process. Definition 2 gives the information that is available in the training data set. Based on the information in the training data set, we calculate the relative affinity measurements of the images in the image database (as shown in Definition 3).

Definition 2: The training data set consists of the following information:

• *The value N that indicates the number of images in the image database d.*

• *A set of queries* $Q = \{q_1, q_2, \ldots, q_q\}$ *that are issued to the database in a period of time. Each query shows the access patterns and access frequencies of the images. Let* $use_{m,k}$ *denote the usage pattern of image m with respect to query* q_k *per time period, where the value of* $use_{m,k}$ *is 1 when m is accessed by* q_k*, and 0 otherwise. The value of* $access_k$ *denotes the access frequency of query* q_k *per time period.*

Definition 3: The relative affinity measurements indicate how frequently two images are accessed together. The relative affinity relationship between two images m and n is defined as follows:

$$aff_{m,n} = \sum_{k=1}^{q} use_{m,k} \times use_{n,k} \times access_k \qquad (1)$$

Table 3 gives eight example queries issued to the image database with their corresponding access frequencies. The access patterns of the three sample images in the database versus the eight example queries are shown in Table 4. In this table, the entry $(i, j) = 1$ indicates that the i^{th} image is accessed by the j^{th} query (i.e., q_j).

Matrix A: The State Transition Probability Distribution

The state transition probability distribution (matrix A) is constructed by having $a_{m,n}$ be the element in the $(m, n)^{th}$ entry in A, where:

$$a_{m,n} = \frac{f_{m,n}}{f_m} \qquad (2)$$

$$f_{m,n} = \frac{aff_{m,n}}{\sum_{m \in d} \sum_{n \in d} aff_{m,n}} \qquad (3)$$

$$f_m = \sum_n f_{m,n} \qquad (4)$$

In this formulation, $f_{m,n}$ is the joint probability that refers to the fraction of the relative affinity of images m and n in the database d with respect to the total relative affinity for all the images in d, f_m is the marginal probability, and $a_{m,n}$ is the conditional probability that refers to the state transition probability for an MMM.

Matrix Π: *The Initial State Probability Distribution*

The preference of the initial states for queries can be obtained from the training traces. For any image

Table 3. Eight example queries and their frequencies ($access_k$)

$m \in d$, the initial state probability is defined as the fraction of the number of occurrences of image m with respect to the total number of occurrences for all the images in d from the training traces.

$$\Pi = \{\pi_m\} = \frac{\sum_{k=1}^{q} use_{m,k}}{\sum_{l=1}^{N}\sum_{k=1}^{q} use_{l,k}} \qquad (5)$$

Stochastic Process for Information Retrieval

The need for efficient information retrieval from databases is strong. Usually the cost for query processing is expensive and time-consuming. Meanwhile, the results may not be very satisfactory. Probabilistic models offer a way to perform the searching process more efficiently and accurately. We capture the most matched images through a dynamic programming algorithm that conducts a stochastic process in calculating the current edge weights and the cumulative edge weights.

Assume N is the total number of images in the databases and each query is denoted as *query* = $\{o_1, o_2, \ldots, o_T\}$, where T is the total number of features requested in the query. We define the edge weights and the cumulative edge weights as follows.

Definition 4: $W_t(i, j)$ is defined as the edge weight of the edge $S_i \rightarrow S_j$ at the evaluation of the t^{th} *feature* (o_t) *in the query, where* $1 \le i, j \le N$ *and* $1 \le t \le T$.

Definition 5: $D_t(i, j)$ is defined as the cumulative edge weight of the edge $S_i \rightarrow S_j$ at the evaluation of the t^{th} *feature* (o_t) *in the query, where* $1 \le i, j \le N$ *and* $1 \le t \le T$.

Based on Definitions 4 and 5, the *dynamic programming algorithm* is given as follows:

At $t = 1$, we define

$$W_1(i, j) = \begin{cases} \pi_{S_i} b_{S_i}(o_1) & i = j \\ 0 & otherwise \end{cases} \quad (6)$$

$$D_1(i, j) = W_1(i, j) \quad (7)$$

The values of $W_{t+1}(i, j)$ and $D_{t+1}(i, j)$, where $1 \leq t \leq T - 1$, are calculated using the values of $W_t(i, j)$ and $D_t(i, j)$ as follows:

$$W_{t+1}(i, j) = \max_k (D_t(k, i) a_{S_i, S_j}) b_{S_j}(o_{t+1}) \quad (8)$$

$$D_{t+1}(i, j) = (\max_k D_t(k, i)) + W_{t+1}(i, j) \quad (9)$$

As we mentioned before, $\mathcal{A} = \{a_{S_i, S_j}\}$ denotes the states transition probability distribution, $\mathcal{B} = \{b_{S_j}(o_k)\}$ is the observation symbol probability distribution, and $\Pi = \{\pi_{S_i}\}$ is the initial state probability distribution.

The image retrieval steps using the dynamic programming algorithm in the stochastic process are shown in Table 5. As can be seen from the result, our method can give a good ordering using this stochastic process.

In Step 3, since we already obtained matrices $W_1(i, j)$ and $D_1(i, j)$ from Step 2, and the second feature o_2 is known, the content of $W_2(i, j)$ and $D_2(i, j)$ can be determined. The value of $D_t(i, j)$ (obtained in Step 4) represents the cumulative edge weight for the joint event that $\{o_1, o_2, \ldots, o_T\}$ is observed. In the filtering step (Step 6), $D_T(q, j)$ together with $sumD_t(j)$ (where $1 \leq t \leq T$) are used as the filter to retrieve the candidate images with respect to query image q. In this step, when there are images with identical $D_T(q, j)$ values, we go to the matrix $sumD_T(j)$ to find different values to order them. If we fail to order them by the values in $sumD_T(j)$, we have to trace down to the next matrix $sumD_{T-1}(j)$ and continue the process until we reach the first matrix $sumD_1(j)$. We also take into consideration the characteristics of $sumW_t(j)$. From our observations, if the j^{th} image does not have the t^{th} feature in the query, the value of $sumW_t(j)$ would be zero. Taking advantage of this characteristic, we can exclude some of the images that do not have any feature desired in the query from the final result. Therefore, in Step 7, we use $W_T(q, j) + W_T(j, q)$ to reflect the possibility that the j^{th} image matches the issued query. In other words, it indicates the matching percentage of the j^{th} image in the image database to the query image q with respect to the features $\{o_1, o_2, \ldots, o_T\}$.

EXPERIMENTS

Experimental Image Database System

In our image database, there are 1,500 color images of various dimensions that are used to carry out the experiments. With the purpose of supporting semantic level meaning in the users' queries, both the color information and object location information are considered in our experiments. In addition, the query-by-example strategy is used for query issuing in our experiments. Based on the training data set of this image database, first we need to construct the model parameters for the MMM mechanism for the database.

Constructions of the Model Parameters

Each MMM has three probability distributions ($\mathcal{A}$, $\mathcal{B}$, and Π). The state transition probability distribution $\mathcal{A}$ can be obtained according to Equations (1) to (4). In order to calculate $\mathcal{B}$, first we need to construct $\mathcal{BB}$ based on the images and their features in the experimental database. Based on $\mathcal{BB}$, $\mathcal{B}$ can be obtained using the procedure aforementioned. The initial state probability distribution for experimental database can be determined by using Equation (5). The constructions of these model parameters can be performed off-line.

Table 5. Image retrieval steps using the stochastic model

1. Given the query image q, obtain its feature vector $query = \{o_1, o_2, \ldots, o_T\}$, where T is the total number of non-zero features of the query image q.
2. Upon the first feature o_1, calculate $W_1(i, j)$ and $D_1(i, j)$ according to Equations (6) and (7).
3. Move on to calculate $W_2(i, j)$ and $D_2(i, j)$ according to Equations (8) and (9).
4. Continue to calculate the next values for the W and D matrices until all the features in the query have been taken care of.
5. Upon each feature in query, we can obtain a pair of matrices: $W_t(i, j)$ and $D_t(i, j)$. We then sum up each column in matrices $W_t(i, j)$ and $D_t(i, j)$. Namely, we calculate $sumW_t(j) = \sum_i W_t(i, j)$ and $sumD_t(j) = \sum_i D_t(i, j)$.
6. Find the candidate images by sorting their corresponding values in $D_t(q, j)$, $sumD_T(j)$, $sumD_{T-1}(j)$, …, or $sumD_1(j)$. First, an image is ranked according to its value in $D_T(q, j)$. If there exist several images that have the same value, then $sumD_T(j)$ values are used for ranking. If several images have the same $sumD_T(j)$ value, then $sumD_{T-1}(j)$ values are used and the process continues until $sumD_1(j)$.
7. Select the top ranked images from the output of Step 6, and rank them to the user based on their values in $W_T(q, j) + W_T(j, q)$.

Once the model parameters of the MMM for the image database is constructed, the stochastic process shown in Table 5 is used for image retrieval.

Stochastic Process for Example Queries

For a given query image issued by a user, the stochastic process with the proposed dynamic programming algorithm will be carried on to dynamically find the matched images for the

user's query. A series of W_t and D_t matrices are generated according to Equations (6) to (9). The qualifying degrees of the images with respect to the certain query image are estimated by the values in the resulting W_t and D_t matrices according to rules described in Table 5.

In this section, we use a set of example queries to demonstrate the effectiveness of our stochastic model. For each set of query results, the qualifying possibilities of the images are in the descending order from the *top left* to the *bottom right*. The searching results are listed and analyzed as well. As can be seen from the experimental results, our method effectively extracts the images that contain the features specified in the query image and ranks them appropriately.

Query I

In this query example, the query image #2265 has one color feature and one location feature which are 'blue' (b) and 'L5.' Exhibit 1 gives the corresponding $\mathcal{B}$ matrix entry for it.

Since there are two features in the query image, two *W* matrices and two *D* matrices will be generated. The system is supposed to return those images that have the desired features in the ordering of similarity. The snapshot of the retrieval result screen containing the top 12 images is shown in Figure 3. As can be seen from this figure, the 'blue' color is the dominating color in all the retrieved images. Moreover, they all have an object located at 'L5' (the centre location). It should also be noted that some images are excluded from the query results because their values in $sumW_T(j)$ are zeros, which means they do not have the corresponding features ('blue' or 'L5').

Query II

In this query, the major features of this query image include four components: 'blue' (b), 'white' (w), 'yellow-green' (yg), and 'L5' (the centre location) with the $\mathcal{B}$ matrix in Exhibit 2.

The most qualified images to this query are those that have all of the above three-color features and an object at the L5 location (i.e., the centre location). Images that have only one of the desired features are less satisfactory. The snapshot of this example query is given in Figure 4. All the retrieved top 12 images have the above mentioned color features and have the object(s) at location 'L5.'

Exhibit 1.

	black	w	red	ry	y	yg	green	gb	b	bp	p	pr	L1	L2	L3	L4	L5	L6	L7	L8	L9
img2265	0	0	0	0	0	0	0	0	0.5	0	0	0	0	0	0	0	0.5	0	0	0	0

Figure 3. Snapshot of Query I

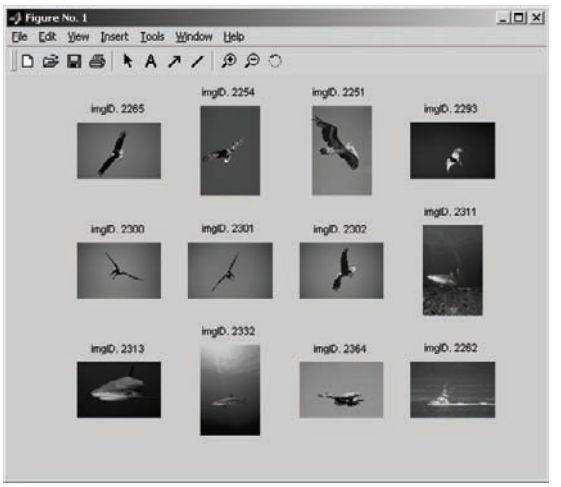

Exhibit 2.

black	w	red	ry	y	yg	green	gb	b	bp	p	pr	L1	L2	L3	L4	L5	L6	L7	L8	L9
0	0.17	0	0	0	0.17	0	0	0.16	0	0	0	0	0	0	0	0.5	0	0	0	0

Query III

Similar to the previous query example, there are four features, which are 'red,' 'purple-red,' 'L1,' and 'L5.' Two of them are the color features and the other two are the object location descriptions. Figure 5 exhibits the top 24 images retrieved from the image database. The final query results are good and the ranking is reasonable.

FUTURE TRENDS

The current CBIR systems are promising and reflect the increasing interest in the field of content-based image retrieval. However, there are still a number of open research issues to be addressed. For example, it is critical to develop the suitable evaluation criteria and benchmarks for CBIR systems. Some future trends include:

- *Automatic or semi-automatic methods of object extraction for image retrieval:* It has been recognized that the searching for images in large databases can be greatly facilitated by the use of semantic information such as object location and type. However, using the current technique of computer vision cannot extract the object information easily. For example, even though the unsupervised image segmentation is applied in our framework to obtain the object informa-

Figure 4. Snapshot of Query II

Figure 5. Snapshot of Query III

tion, we still have to find a trade-off between the accuracy and performance. Considering that users may upload their own query image (which is not in the database) during the content-based retrieval, the real-time feature extraction could be a big issue to affect the users' will to use the system. There is an increasing need to derive more efficient yet good enough methods of segmenting images to distinguish objects of interest from their background. The main goal is to bridge the semantic gap, bringing some measure of automation to the processes of indexing and retrieving images by the type of object or scene depicted.

- *Indexing standard and query language support for image databases:* Currently, there are neither the standards in indexing the features and the subject taxonomies for image databases, nor the standard for hierarchical representation of an image when taking into consideration the objects inside the image. These standards are essential in expressing complex semantics and supporting the manipulation of content-based queries on image objects. Once the feature representations of image objects follow the same standards, it becomes possible to develop a suitable query language exclusively designed for image databases.
- *Support for automatic video indexing and retrieval:* Recently, lots of research work has been done on automatic video segmentation. After video is segmented into smaller units such as shots or scenes, each unit is represented by its key frames. Then, the complex spatial-temporal semantics can be obtained by parsing the content of these key frames, which forms the basis for supporting advanced video retrieval techniques such as query-by-motion facilities. MPEG-7 (Moving Picture Experts Group) standard (*http://media.wiley.com/product_data/excerpt/87/04714867/0471486787.pdf*) is the first to take into consideration the issue of multimedia content representation. This standard will define a standard for describing every aspect of the content of a multimedia object, including the specifications of a video's image features. MPEG-7 will definitely have an impact on CBIR and will probably guide the development of future CBIR systems.
- *Better user interaction, especially the improved techniques for collecting users' feedback:* User's relevance feedback has been adopted in most recent efforts towards the research of CBIR. In order to get better results, the user may be asked to browse a bunch of images through iterations and to provide the detailed ranking for similarity for the images. The fact is that a heavy and unnecessary burden of responsibility is brought to the user. In addition, it is highly probable that this burden will have a negative effect on a user's perception of the effectiveness and efficiency of the system.

CONCLUSION

Currently, Content-Based Image Retrieval (CBIR) technology is still immature but with great potential. In this chapter, a review of the recent efforts and techniques in CBIR is given, followed by the discussion of the current problems in the CBIR systems from the efficiency concern of the searching process. In response to this issue, in this chapter, the Markov model mediator (MMM) mechanism is applied to the image databases for content-based image retrieval. A stochastic process based on the MMM mechanism is proposed to traverse the database and find the similar images with respect to the query image. This approach performs similarity comparison based on not only the relationship between the query image and the target image, but also the relationships among all the images within the database, such as their access patterns and access frequencies. Joint color/layout similarity measurement is supported in this system to offer more complete distinction descriptions of the images and better retrieval effectiveness. Several experiments were conducted and the experimental query-by-example image query results to the proposed retrieval system were reported. The fact that the proposed stochastic content-based CBIR system utilizes the MMM mechanism and supports both spatial and color information offers more flexible and accurate results for user queries. The experimental results exemplify this point and the overall retrieval performance of the presented system is promising. Besides modelling the relationship of

image objects within a single database, the MMM mechanism also has the capability (although not shown in this chapter) to model the relationships among distributed image databases so as to guide the efficient search across the distributed image databases.

Chapter 7.12
A Spatial Relationship Method Supports Image Indexing and Similarity Retrieval

Ying-Hong Wang
Tamkang University, Taiwan

ABSTRACT

The increasing availability of image and multimedia-oriented applications markedly impacts image/multimedia file and database systems. Image data are not well-defined keywords such as traditional text data used in searching and retrieving functions. Consequently, various indexing and retrieving methodologies must be defined based on the characteristics of image data. Spatial relationships represent an important feature of objects (called icons) in an image (or picture). Spatial representation by 2-D String and its variants, in a pictorial spatial database, has been attracting growing interest. However, most 2-D Strings represent spatial information by cutting the icons out of an image and associating them with many spatial operators. The similarity retrievals by 2-D Strings require massive geometric computation and focus only on those database images that have all the icons and spatial relationships of the query image. This study proposes a new spatial-relationship representation model called "Two Dimension Begin-End boundary string" (2D Bε-string). The 2D Bε-string represents an icon by its MBR boundaries. By applying "dummy objects," the 2D Bε-string can intuitively and naturally represent the pictorial spatial information without any spatial operator. A method of evaluating image similarities, based on the modified "Longest Common Subsequence" (LCS) algorithm, is presented. The proposed evaluation method can not only sift out those images of which all icons and their spatial relationships fully accord with query images, but for those images whose icons and/or spatial relationships are similar to those of query images. Problems of uncertainty in the query targets and/or spatial relationships thus solved. The representation model and similarity evaluation also simplify the retrieval progress of linear transformations, including rotation and reflection, of images.

INTRODUCTION

The increasing availability of image and multimedia-oriented applications very significantly influences image/multimedia file and database systems. Image data are not well-defined keywords such as traditional text data used in searching and retrieving functions. Therefore, various indexing and retrieving methodologies have to be defined based on the characteristics of image data.

Abstracting the information in original images is very important in pictorial spatial application systems. These abstractions include how the image icons and their characteristics were recognized; how the symbolic image was encoded and constructed; how to index and retrieve these images; how to evaluate their similarity corresponding to a query image, and many others. All of these are very important issues in information and content-based retrieval.

Three basic types for image indexing and retrieval exist: (1) by features, for example, color, texture, or shape, of the icons in the images, as in the QBIC project (Huang & Jean, 1994), and the Virage search engine (Liang & Mou, 1996); (2) by size and location of the image icons, as in R-tree (Guttman, 1984), R*-tree (Beckmann, Kriegal, Schneider, & Seeger, 1990), Quadtree (Samet, 1989), and Mou's similarity method (Chien, 1998); (3) by relative position of the icons (called Spatial relationship), as in 2-D String (Chang, Shi, & Yan, 1987) and its variants (Chang, Jungert, & Li, 1988; Lee & Hsu, 1990; Lee, Yang, & Chen, 1992; Bach, et al., 1996; Liang & Mou, 1997; Hsu, Lee, & Lin, 1999; Sipser, 1997; Papadias & Theodoridis, 1995). Spatial relationships represent an important feature of objects (called icons) in an image (or picture).

The third type is most suited to those applications that are independent of the actual coordinates of icon objects, as in for example, 'find all images in which icon *A* is located on the left side and icon *B* on the right.' Spatial representation by 2-D String and its variants, in a pictorial spatial database, has attracted increasing attention. However, most of 2-D Strings represent the spatial information by cutting the icons out of an image, which are associated with many spatial operators. Their similarity retrievals require extensive geometric computation and focus only on those database images that include all of the icons and spatial relationships of the query image.

This investigation proposes a novel spatial knowledge representation model called, "Two Dimension Begin-End boundary string (2D Bε-string)." The 2D Bε-string need not cut any image's icons because it directly represents an icon by the boundaries of its MBR (Minimum Bounding Rectangle). By applying "**dummy** objects," the 2D Bε-string can intuitively and naturally represent the pictorial spatial information without any spatial operators. An algorithm is also introduced, which involves $\boldsymbol{O(n)}$ space complexity in the best and worst case, to establish an image database using the proposed model.

A method of evaluating image similarities is also presented, according to the modified "Longest Common Subsequence" (LCS) algorithm (Cormen, Leiserson, & Rivest, 1990). The proposed evaluation method sifts out not only those images in which all of the icons and their spatial relationships fully accord with those of the query images, but also those images whose icons and/or spatial relationships are similar to those of the query image. Problems of uncertainty of the query targets and/or spatial relationships are thus solved. The modified LCS algorithm involves $\boldsymbol{O(mn)}$ space and time complexity, where m and n are the numbers of icons in a query image and a database image, respectively. Retrieving the linear transformations of an image represented by a 2D Bε-string is simpler than other models of 2-D Strings. The transformations include 90, 180, 270 degrees clockwise rotations and reflections in the x- and y-axis.

The rest of this chapter is organized as follows. The chapter reviews the approaches of 2-D String and its variants and is followed with a section that

proposes a new spatial knowledge representation model, called 2D Bε-string, and an algorithm to construct a symbolic picture using 2D Bε-string. Then, the chapter introduces a similarity retrieval algorithm, modified from LCS, and the corresponding similarity evaluation process. Next, the chapter presents a demonstration system, which is a visual retrieval system, implemented by 2D Bε-string and the modified LCS algorithm. The chapter finishes with concluding remarks and suggests directions for future work.

BACKGROUND

This section introduces relevant background theories and techniques.

Minimum Bounding Rectangle (MBR)

MBR is the most popular approximation to identify an object from images (Papadias & Theodoridis, 1995; Bowen & Um, 1999; Song, Whang, Lee, & Kim, 1999; Orlandic & Yu, 2000), and retains the most important characteristics of the object; position and extension. MBR is characterizes an object by minimum and maximum *x* and *y* coordinates (Zimbrao & De Souza, 1998). Figure 1 presents a coordinate system for a picture/image considered in this chapter. Symbols minX(*A*) and maxX(*A*) are minimum and maximum *x* coordinates of the MBR for an object, *A*. Symbols minY(*A*) and maxY(*A*) are minimum and maximum *y* coordinates of the MBR for an object, *A*.

Representation Models of 2-D String and its Variants

Chang, Shi and Yan (1987) proposed an approach, called '2-D String', to represent the spatial information of a picture or image. The 2-D String uses a symbolic projection of a picture on the *x*- and *y*-axes. They define two sets of symbols, *V* and *A*. Each symbol in *V* presents an icon object in an image. *A* is a set of spatial operators containing {'=', '<', ':'}. A 2-D String over *V* and *A* is defined by $(u, v) = (o_1x_1o_2x_2\ldots x_{n-1}o_n, o_{p(1)}y_1o_{p(2)}y_2\ldots y_{n-1}o_{p(n)})$, where $o_1o_2\ldots o_n$ is a 1-D string over *V*, $x_1x_2\ldots x_{n-1}$ and $y_1y_2\ldots y_{n-1}$ are 1-D strings over *A*; $o_{p(1)}o_{p(2)}\ldots o_{p(n)}$ is a permutation of $o_1o_2\ldots o_n$ on the *y*-axis. Therefore, *n* icon objects are in the picture/image and their spatial information is represented by operators, $x_1x_2\ldots x_{n-1}$ and $y_1y_2\ldots y_{n-1}$ on *x*-axis and *y*-axis, respectively. Figure 2 depicts an example of 2-D String.

The 2D G-string (Chang, Jungert, & Li, 1988), a variant of 2-D String, extends spatial relationships to two sets of spatial operators, R_l and R_g, and cuts all the objects along their MBR boundaries. The set, R_l, defines local spatial relationships that are partially overlapping projections between two objects. The set, R_g, defines global spatial relationships, such that the projection of two objects are disjoining, adjoining or in the same position.

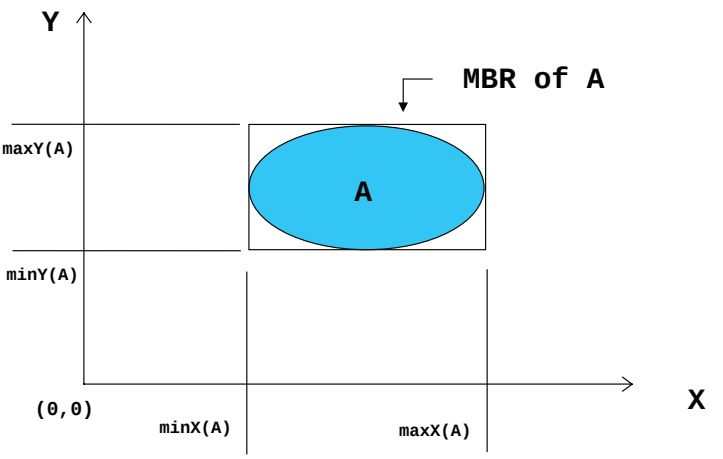
The 2D C-string (Lee & Hsu, 1990; Bach, et al., 1996), another variant of 2-D String, minimizes the number of cutting objects. The 2D C-string keeps the leading object uncut and addresses the problem of superfluous cutting objects generated by 2D G-string cutting progress. The worst case will involve $O(n^2)$ cutting objects.

Consequently, the 2D B-string (Lee, Yang, & Chen, 1992) does not use cutting, and instead, represents an object by two symbols. One of which indicates for the beginning boundary of that object; the other one represents the end. 2D B-string also reduces the spatial relationships to a single operator '=', such that two objects have the same boundary projection if '=' appears.

Similarity Retrieval and Evaluation

The basic similarity retrieval and evaluation approaches of 2-D String (Chang, Shi, & Yan, 1987), 2D G-string (Chang, Jungert, & Li, 1988), 2D C-string (Lee & Hsu, 1990) and 2D B-string (Lee, Yang, & Chen, 1992) are the same (Chan & Chang, n.d.). First, they always define three types

Figure 1. MBR presentation of an object in a picture/image



of similarity, type-*i* (*i* = 0, 1, 2). Each is constrained according to some conditions. Type-1 is stricter than type-0; type-2 is stricter than type-1. Second, they compare all spatial relationship pairs between any two objects in the query image to pairs in an image in databases and build a type-*i* subgraph if the pair satisfies type-*i* constraints. Then, they find the **maximum complete subgraph** from each existing type-*i* graph. The number of objects in the maximum complete subgraph measures the similarity of the query image to images in databases.

The space and time complexity of examining all spatial relationship pairs is $O(n^2)$, where n is the number of objects in an image. Finding the maximum complete subgraph is an NP-complete problem (Kim & Um, 1999), and is a time consuming procedure is not suited to a large number of icon objects in an image.

SPATIAL REPRESENTATION MODEL USING 2D Bε-STRING

2D Bε-string Model

Several approaches have been proposed to represent an icon in an image. These include MBR (Minimum Bounding Rectangle) (Chang, Jungert, & Li, 1988; Lee & Hsu, 1990; Lee, Yang, & Chen, 1992; Bach, et al., 1996), MBE (Minimum Bounding Ellipse), MBC (Minimum Bounding Circle) (Chien, 1998), and others.

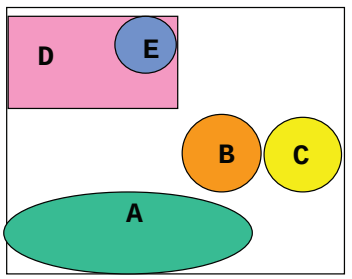
The approach presented here, 2D Bε-string, is based on MBR. Conceptually, it is similar to the 2D B-string approach. Both represent an object by its MBR boundaries and require nothing to be cut. However, 2D Bε-string states the spatial relationship between two boundary symbols in quite a different way. 2D B-string uses a **spatial operator** (=) to denote an **IDENTITY** between the projections of two boundaries. In 2D Bε-string, a **dummy object** is used to describe the **DISTINCTION** between the projections of two boundaries.

The definition of 'Dummy Object' is as follows:

A 'Dummy Object' is an assumed virtual object; it is not a real object existing in an original image. It can be specified as any size of space and be memorized as symbol 'ε'.

2D Bε-string can be defined as:

Figure 2. Example of 2D string representation



The 2D String is

(A=D:E<A=B<C, A<B=C<D:E)

$(u, v) = (d_0x_1d_1x_2d_2\ldots d_{n-1}x_nd_n,\ d_0y_1d_1y_2d_2\ldots d_{n-1}y_nd_n)$

where d_i is a dummy object ε, or a null string, $i = 0, 1, \ldots n$, and x_i and y_i are real icon objects which are either beginning or ending projected boundaries on the *x*- and *y*-axis, respectively, with $i = 1, 2, \ldots n$. d_i can be determined when the maximum size of an image, say X_{max} and Y_{max} along the *x*- and *y*-axes, respectively, is known. Set d_0 to ε if a space exists between the beginning boundary of the leftmost (bottommost) object and the left (bottom) edge of the image. Similarly, set d_n to ε if an interval exists between the ending boundary of the rightmost (topmost) object and the right (top) edge of the image. For the dummy objects, set d_i to ε if the boundary projections of x_i and x_{i+1} (y_i and y_{i+1}) differ from each other.

The 2D Bε-string in Figure 3, for example, is written as $(u, v) = (\varepsilon A_b \varepsilon B_b \varepsilon A_e C_b \varepsilon C_e \varepsilon B_e \varepsilon, \varepsilon B_b \varepsilon A_b \varepsilon B_e C_b \varepsilon C_e \varepsilon A_e \varepsilon)$. The dummy object, d_0, was set to ε because a space exists in front of the beginning boundary of object *A* on the *x*-axis. The dummy object d_6 was also set to ε because a space is in the behind object, *B*, on the *x*-axis. However, the dummy object, d_3, was set to null string, because the ending boundary of object *A* and the beginning boundary of object *C* are projected onto the same point on the *x*-axis. A similar case applies to the ending boundary of object *B* and the beginning boundary of object *C* on the *y*-axis.

Observably, 2D Bε-string has the following advantages:

First, the object location in the original image and the symbolic picture are mapped directly, as show in Table 1. No operator is required to represent the spatial relationship between objects. The approach is intuitive.

Second, this approach of 2D Bε-string does not need to cut the objects from the image. It simplifies the construction of the image database. The space complexity for an image with *n* objects in the worst and best case is *O*(n). In the worst case, all boundary projections are distinct and a space is left in the leftmost, bottommost, rightmost and topmost parts of an image ($4n+1$ symbols are required). In contrast, in the best case, all boundary projections are identical and exactly fit in an image (requiring $2n+1$ symbols only).

Third, the approach simplifies similarity retrieval because results of spatial reasoning need not be combined.

Algorithm for Constructing a Symbolic Picture

By default, before converting an image to a symbolic picture represented by 2D Bε-string, all objects and their MBR coordinates must be abstracted from that image. Then, algorithm **Convert-2D-Bε-String**, shown in Table 2, is called to transform an original image into a symbolic picture. Lines one to 12 explain the meaning of the variables used in the input parameters and the conversion process. Lines 14 to 19 separately sort the input data by key coordinate and object identifiers, in ascending order on the *x*- and *y*-axes. Lines 21 to 32 construct the 2D Bε-string on the *x*-axis, and lines 34 to 45 construct the 2D Bε-string on the *y*-axis.

The time complexity of algorithm **Convert-2D-Bε-String** depends on the sorting algorithm in line 19. The time complexity of loops in lines 14 to 18, 24 to 30 and 37 to 43 is $O(n)$, and never exceeds that of the sorting algorithm. Ignoring the sorting algorithm, the space complexity of this algorithm is also $O(n)$.

Building an image database using 2D Bε-string, requires only algorithm **Convert-2D-Bε-String** to be called with the MBR coordinates and object identifiers of each image and the results of the 2D Bε-string to be saved in the database. Saving the 2D Bε-string with the MBR coordinates of objects in an image allows the location into which a new object is to be inserted and the MBR boundaries of that object to be easily found using the binary search method with MBR coordinates and the identifier of the new object as searching keys. This is because the 2D Bε-string uses an order datum to represent the relationship among the objects in an image. Whether a dummy object is to be inserted around this new object boundary is easy to determine. In contrast with insertion, dropping an object from an image, requires the dropping object to be searched sequentially from the 2D Bε-string data. It is a direct deletion and the redundant dummy object, if found, to be deleted.

Figure 3. Image with three objects

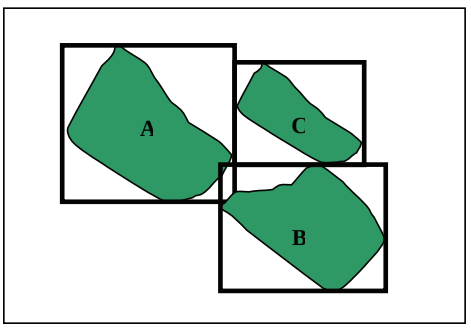


IMAGE SIMILARITY RETRIEVAL AND EVALUATION

Assessment of Similarity

The "Background" section discussed the symbolic image construction and the assessment of similarity, using 2D B-String. In order to decide which type, type-0, type-1 or type-2, of similarity it belongs to all spatial relationships for every pair of objects in a database image must be recorded to determine of which type is the similarity. However, this assessment does not address a situation in which only a few query objects are present in a database image. Moreover, the assessment of similarity as type-0, type-1 and type-2 is based on the maximum complete subgraph. Obtaining a maximum complete subgraph from C_2^m spatial relationships of m objects in a query image and C_2^n spatial relationships of n objects in the database image is rather time-consuming.

This chapter also uses the number of spatial relationships, formed by every pair of objects that simultaneously appear in the query image and the database image, as the assessment of similarity. However, the proposed method does not find a maximum complete subgraph but finds a longest common subsequence (LCS) (Cormen, Leiserson,

& Rivest, 1990) of two 2D Bε-strings instead. After the LCS string is found, it is evaluated in relation to 2D Bε-strings of the query image and the database image.

The motivations for finding an LCS string in this work and finding a maximum complete subgraph in 2-D Strings from two images are different tunes rendered with equal skill. Both the LCS string and the subgraph are used to evaluate similarity. However, the time complexity of an LCS algorithm is $O(mn)$, where m and n are the number of objects in the query image and the database image, respectively. The complexity depends only on the length of 2D Bε-string in the query image and the database image. Not all the spatial relationships need be examined for every pair of objects because **"in the query image and the database image, all spatial relationships of every pair of objects in the LCS string are identical."** Therefore, similarity can be evaluated in a reasonable time.

Table 1. Mapping of spatial relationships

	In symbolic picture	In original image
1	$\varepsilon A_b \varepsilon A_e \varepsilon C_b \varepsilon C_e \varepsilon$	
2	$\varepsilon A_b \varepsilon A_e C_b \varepsilon C_e \varepsilon$	3	$\varepsilon A_b \varepsilon C_b \varepsilon A_e \varepsilon C_e \varepsilon$	4	$\varepsilon A_b \varepsilon C_b \varepsilon C_e A_e \varepsilon$	5	$\varepsilon A_b \varepsilon C_b \varepsilon C_e \varepsilon A_e \varepsilon$	
6	$\varepsilon A_b C_b \varepsilon A_e \varepsilon C_e \varepsilon$	7	$\varepsilon A_b C_b \varepsilon A_e C_e \varepsilon$	8	$\varepsilon A_b C_b \varepsilon C_e \varepsilon A_e \varepsilon$	9	$\varepsilon C_b \varepsilon A_b \varepsilon A_e \varepsilon C_e \varepsilon$	10	$\varepsilon C_b \varepsilon A_b \varepsilon A_e C_e \varepsilon$	11	$\varepsilon C_b \varepsilon A_b \varepsilon C_e \varepsilon A_e \varepsilon$	12	$\varepsilon C_b \varepsilon C_e A_b \varepsilon A_e \varepsilon$	13	$\varepsilon C_b \varepsilon C_e \varepsilon A_b \varepsilon A_e \varepsilon$	

Algorithms of Similarity Retrieval

This study presents an algorithm to find the longest common subsequence length of two 2D Bε-strings. Table 3 shows this algorithm, which is called, **2D-Bε-LCS-Length**. The algorithm is modified from the LCS algorithm in Cormen, Leiserson and Rivest (1990). Revising the original LCS algorithm depends on two considerations. First, LCS is prevented from picking dummy objects continuously, because a single dummy object sufficiently represents the relative spatial relationship between two boundary symbols. The *if*-statement in line 21 performs this evaluation. Second, the LCS paths-recording matrix in the original LCS algorithm is omitted by evaluating left and up paths first, as shown in lines 16 to 19, and then evaluating the left-up diagonal path, as shown lines 23 to 24. The LCS path can still be inferred from the matrix record of the LCS length.

Algorithm **2D-Bε-LCS-Length** uses two 2D Bε-strings, *Q* and *D*, as input parameters — one for the query image and the other one for the database image. The 2D Bε-string of a query image with *m* objects in, each dimension has 2*m* boundary symbols and up to 2*m*+1 dummy objects. The maximum length of a 2D Bε-string in each dimension is 2*m*+(2*m*+1), that is, 4*m*+1. The maximum length of 2D Bε-string of a database image with *n* objects is similarly derived as 4*n*+1. The LCS length-inferring table *W*, requires (1+(4*m*+1))(1+(4*n*+1)) storage units; therefore, the space complexity is *O*(*mn*).

Lines seven to eight and 10 to 11 of the algorithm in Table 2 show the initialization of the first row and first column in the LCS-length inferring table, *W*: each string symbol must be set once. These instructions are executed 4*m*+1 and 4*n*+2 times, respectively. The outer loop, in line 13, examines each row in *W*, 4*m*+1 times. The inner loop, in lines 14 to 26, examines each cell of *W*, (4*m*+1)*(4*n*+1) times. Thus, the time complexity is *O*((4*m*+1)+ (4*n*+2)+(4*m*+1)*(4*n*+1)) the same as *O*(*mn*).

A recursive procedure is also specified for printing the longest common subsequence string of two 2D Bε-strings. Table 4 shows this algorithm. The initial invocation is **Print-2D-Bε-LCS** (*Q*, *W*, *length*(*Q*), *length*(*D*)). From the value of the last cell in the LCS-inferring table, *W*, this procedure decreases by *i* and/or *j* in the left and/or up direction in each recursive call, until either *i* or *j* reaches zero. Then, all symbols of the LCS string are printed out in the proper, forward order.

To find the longest common subsequence length of two 2D Bε-strings, the LCS string length of the current cell must be compared with that of the top one before the LCS string symbol is printed, according the revised procedure shown as Table 3. Therefore, the LCS path is determined from the up direction if the LCS string lengths are equal. The corresponding boundary symbol or dummy object is not a symbol of the LCS string. This symbol is thus ignored and is induced continuously along the up direction, as shown in lines five to six. However, if the lengths are unequal, the current cell's LCS string length must be compared with the left cell's length. If these lengths are the same, then the LCS is induced from the left direction. For the same reason as in the preceding case, if the corresponding boundary symbol or dummy object is not a symbol of the LCS string, this symbol is ignored and is induced continuously along the left direction, as shown in lines seven through eight. If the LCS is from neither the up nor the left direction, it must be induced from the left-up diagonal direction. The boundary symbol or dummy object associated with the current cell must be part of the LCS string. After recursively processing all the cells in the left/up direction, this symbol in the LCS string is printed out, as shown in lines nine to 11.

Lines six, eight and 10 are recursively called; each time, either *i* or *j* is reduced by one. This algorithm can print out all LCS string symbols after no more than *m*+*n* recursions. The time complexity is *O*(*m*+*n*).

Similarity Evaluation

After the LCS length and the LCS string are obtained from the query image and data images in each dimension of 2D Bε-string, how is similarity evaluated? Conceptually, the two images are more similar if the LCS string is longer. For example, the strings in one dimension of 2D Bε-string are:

Query image 1: $\varepsilon B_b \varepsilon C_b \varepsilon B_e \varepsilon A_b \varepsilon C_e \varepsilon A_e \varepsilon$,
Database image 1: $\varepsilon B_b \varepsilon B_e \varepsilon D_b \varepsilon A_b \varepsilon D_e \varepsilon A_e \varepsilon$,
LCS string 1: $\varepsilon B_b \varepsilon B_e \varepsilon A_b \varepsilon A_e \varepsilon$,
Database image 2: $\varepsilon B_b \varepsilon C_b \varepsilon B_e \varepsilon D_b \varepsilon A_b \varepsilon D_e \varepsilon C_e \varepsilon A_e \varepsilon$,
LCS string 2: $\varepsilon B_b \varepsilon C_b \varepsilon B_e \varepsilon A_b \varepsilon C_e \varepsilon A_e \varepsilon$.

The LCS strings 1 and 2 follow from query image 1 with database images 1 and 2, respectively, according to the LCS-length-inferring algorithm in Table 3 and the LCS path-discovering algorithm in Table 4. For a given query image string, database image 2 yields a better result than database image 1 because LCS string 2 is longer than LCS string 1. However, two database images with the same LCS string length may not have the same degree of similarity. For example:

Query image 2: $\varepsilon B_b \varepsilon C_b \varepsilon B_e A_b \varepsilon C_e \varepsilon A_e$,
Database image 3: $\varepsilon B_b \varepsilon B_e \varepsilon D_b \varepsilon A_b \varepsilon D_e \varepsilon A_e \varepsilon$,
LCS string 3: $\varepsilon B_b \varepsilon B_e A_b \varepsilon A_e$,
Database image 4: $\varepsilon B_b \varepsilon D_b \varepsilon B_e A_b \varepsilon D_e \varepsilon A_e \varepsilon$,
LCS string 4: $\varepsilon B_b \varepsilon B_e A_b \varepsilon A_e$,

The length of LCS strings 3 and 4 is the same, but database image 4 gives a better matching result than database image 3, because query image 2 requires object *B* and object *A* to be adjoined, that is, boundary symbols B_e and A_b must have the same projection. But in database image 3, object *A* is not adjoined to object *B* because spaces exist between boundary symbols B_e and A_b. The interval does not exist in database image 4. Accordingly, database image 4 has a better similarity than database image 3.

Following the above analysis, the similarity of preceding phenomena is assessed. The following notation is first defined over 2D Bε-string:

Table 2. Algorithm to construct a symbolic picture

Convert-2D-Bε -String (n, C, X_b, X_e, Y_b, Y_e, x_{max}, y_{max})

1. / / n …number of objects in an image
2. / / C …object symbols in image, $C = \{c_1, c_2, \ldots, c_n\}$
3. / / X_b …begin boundaries on x-axis, $X_b = \{x_{b1}, x_{b2}, \ldots, x_{bn}\}$
4. / / X_e …end boundaries on x-axis, $X_e = \{x_{e1}, x_{e2}, \ldots, x_{en}\}$
5. / / Y_b …begin boundaries on y-axis, $Y_b = \{y_{b1}, y_{b2}, \ldots, y_{bn}\}$
6. / / Y_e …end boundaries on y-axis, $Y_e = \{y_{e1}, y_{e2}, \ldots, y_{en}\}$
7. / / x_{max} …maximum coordinate on x-axis
8. / / y_{max} …maximum coordinate on y-axis
9. / / X_{be} …2D Bε-string on x-axis, $X_{be} = \{v_0x_1v_1x_2v_2\ldots v_{n-1}x_nv_n\}$, where v_i = dummy object ε or null string; $i = 0, 1, \ldots, n$; $x_i = c_{bi}$ or c_{ei}, identifies the projection of beging boundary or end boundary of object c_i on x-axis, $i = 1, 2, \ldots, n$
10. // Y_{be} …2D Bε-string on y-axis, $Y_{be} = \{v_0y_1v_1y_2v_2\ldots v_{n-1}y_nv_n\}$, where v_i = dummy object ε or null string; $i = 0, 1, \ldots, n$; $y_i = c_{bi}$ or c_{ei}, identifies the projection of beging boundary or end boundary of object c_i on y-axis, $i = 1, 2, \ldots, n$
11. // S…a sort based on x-axis, $S = \{s_i \mid s_i = x_{bi}c_i$ or $x_{ei}c_i, i = 1, 2, \ldots, 2n\}$
12. // T…a sort based on y-axis, $T = \{t_i \mid t_i = y_{bi}c_i$ or $y_{ei}c_i, i = 1, 2, \ldots, 2n\}$

$$S_x = \begin{cases} 1-(Q_x + D_x - 2L_x)/(4N+1) & \text{if } M_x > 0, \\ 0 & \text{if } M_x = 0; \end{cases}$$

S_y: similarity along *y*-axis, $0 \le Sy \le 1$,

$$S_y = \begin{cases} 1-(Q_y + D_y - 2L_y)/(4N+1) & \text{if } M_y > 0, \\ 0 & \text{if } M_y = 0; \end{cases}$$

S: similarity of the query image to a database image,

S = WxSx + WySy, $0 \le S \le 1$.

The LCS string lengths L_x, L_y, M_x, and M_y can be obtained by the algorithm in Table 3 applied along the *x* and *y* axes. The values of M_x and M_y can be determined as the values L_x and L_y minus the number of dummy symbol, ε, in the LCS string, respectively. W_x and W_y stress the importance of similarity on the *x*-axis and *y*-axis, respectively.

As stated in the section, "2D Bε-String Model", an image with *n* objects has no more than 4*n*+1 symbols on each dimension of its 2D Bε-string. 2*n* symbols are boundary symbols and the rest are 2*n*+1 symbols; dummy objects are dispersed among the boundary symbols. Now each symbol is pictured as a bucket. Thus, an image with *n* objects has up to 4*n*+1 buckets. If the symbol does not exist, then the associated bucket is considered empty. For example, query image 2 with three objects, *A*, *B*, and *C*, has at most 4*3+1=13 symbols. The boundary string is $\varepsilon B_b \varepsilon C_b \varepsilon B_e A_b \varepsilon C_e \varepsilon A_e$. Bucket 7 (Figure 4) is empty due to the lack of a dummy object, ε, between B_e and A_b. The end of a boundary string also lacks a dummy object because the ending boundary of the object *A* is the same as the right-edge of the image; therefore, bucket 13 is empty. In another example, shown in database image 4, the boundary string $\varepsilon B_b \varepsilon D_b \varepsilon B_e A_b \varepsilon D_e \varepsilon A_e \varepsilon$ has an empty bucket 7 (Figure 4).

Comparing the query image (shown as Figure 4) with the database image (shown as Figure 5), buckets in the query image are categorized into four classes and the number of buckets in each class in Table 5 is summarized.

Class I: without a dummy object between two boundary symbols in both the query image and the database image: for example, bucket 7 is empty shown in Figure 4 and Figure 5.

Class II: without a dummy object between two boundary symbols in the query image, but with a dummy object of them in the database image: for example, the ending of boundary string, bucket 13, in the query image (Figure 4), but there is a dummy object in bucket 13 of the database image (Figure 5).

Class III: symbols in the query image but not in the database image; for example, the buckets 4, 5, 10 and 11 show on Figure 4 and Figure 5.

Class IV: symbols with same spatial relationships in both query image and database image; for example, the buckets 1, 2, 3, 6, 8, 9 and 12 present on Figure 4 and Figure 5.

Figure 4. Symbols in buckets of Query Image 2

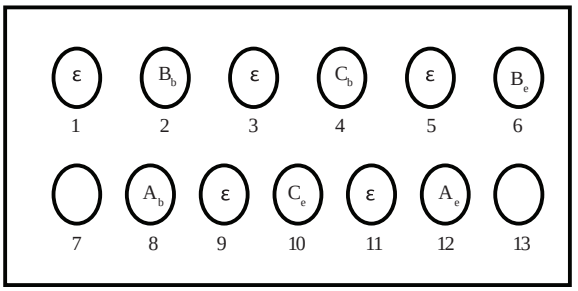

Figure 5. Symbols in bucket of database Image 4

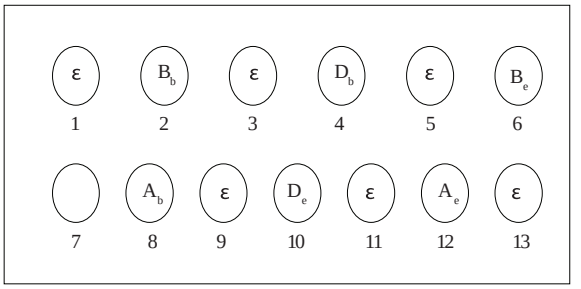

Table 5. Classify by existence of symbol in buckets of a query image

Class	Symbol appears?	The symbol appeared in corresponding bucket in database image?	Number of buckets
I	**No**	**No**	**?**
II N	**o**	**Yes**	**D_x-L_x in *x*-axis, D_y-L_y in *y*-axis**
III	**Yes**	**No**	**Q_x-L_x in *x*-axis, Q_y-L_y in *y*-axis**
IV	**Yes**	**Yes**	**L_x in *x*-axis, L_y in *y*-axis**

Classes I and IV together represent similar parts of a query image and a database image. The evaluated value of similarity can be also obtained from the complementary normalized portion of the total number of buckets in classes II and III. The total number of symbols in class I and IV along the *x*-axis and the *y*-axis are $(4n+1) - (Q_x - L_x + D_x - L_x)$ and $(4n+1) - (Q_y - L_y + D_y - L_y)$, respectively. The similarity on the *x*-axis (S_x) is $1-(Q_x + D_x - 2L_x)/(4n+1)$ and that on the *y*-axis (S_y) is $1-(Q_y + D_y - 2L_y)/(4n+1)$. Clearly, the similarity of the entire image is the sum of S_x and S_y with proper weights adjusting, that is, $S = W_x S_x + W_y S_y$.

Finally, an example is given to detailing the procedure of calculating the similarity. The query image in Figure 3 has three objects, so $N = 3$; the 2D Bε-string is represented as ($\varepsilon A_b \varepsilon B_b \varepsilon A_e C_b \varepsilon C_e \varepsilon B_e \varepsilon$, $\varepsilon B_b \varepsilon A_b \varepsilon B_e C_b \varepsilon C_e \varepsilon A_e \varepsilon$) and the string lengths on the *x*-axis and the *y*-axis, (Q_x, Q_y), are (12, 12), respectively.

The database image in Figure 6 has a 2D Bε-string ($\varepsilon E_b \varepsilon A_b \varepsilon$ $_b \varepsilon A_e \varepsilon C_b \varepsilon F_b \varepsilon E_e \varepsilon C_e \varepsilon B_e \varepsilon F_e \varepsilon$, $\varepsilon E_b \varepsilon B_b \varepsilon E_e \varepsilon A_b \varepsilon B_e C_b \varepsilon F_b \varepsilon C_e \varepsilon A_e \varepsilon F_e \varepsilon$). Table 6 and Table 7 show the LCS-length-inferring table on the *x*-axis and the *y*-axis of the query image and the database image with dummy objects, respectively. The symbols in column q_i and row d_j of Table 6 and Table 7 are the boundary string symbols along the associated axis, with dummy objects in the query image and the database image, respectively. The LCS strings are $\varepsilon A_b \varepsilon B_b \varepsilon A_e C_b \varepsilon C_e \varepsilon B_e \varepsilon$ and $\varepsilon B_b \varepsilon A_b \varepsilon B_e C_b \varepsilon C_e \varepsilon A_e \varepsilon$; thus, the length pair (L_x, L_y) equals (12, 12). The value of (M_x, M_y) can be determined by (L_x, L_y) minus the number

of dummy objects in the LCS string of (L_x, L_y), respectively. The LCS strings of the query image and the database image without dummy objects are $A_bB_bA_eC_bC_eB_e$ and $B_bA_bB_eC_bC_eA_e$; thus, (M_x, M_y) equals (6, 6). The boundary symbols with spatial relationships in the database image, based on strings of M_x and M_y, are $\varepsilon A_b \varepsilon B_b \varepsilon A_e \varepsilon C_b \varepsilon C_e \varepsilon B_e \varepsilon$ and $\varepsilon B_b \varepsilon A_b \varepsilon B_e C_b \varepsilon C_e \varepsilon A_e \varepsilon$; thus, ($D_x$, D_y) equals (13,12). Clearly, the similarity on the *x*-axis and the *y*-axis can be calculated as:

$$\begin{aligned} S_x &= 1-(Q_x + D_x - 2L_x)/(4N+1) \\ &= 1-(12+13-2*12)/(4*3+1) \\ &= 1-(25-24)/13 \\ &= 1-0.0769 \\ &= 0.9231 \end{aligned}$$

$$\begin{aligned} S_y &= 1-(Q_y + D_y - 2L_y)/(4N+1) \\ &= 1-(12+12-2*12)/(4*3+1) \\ &= 1-(24-24)/13 \\ &= 1-0.0 \\ &= 1.0 \end{aligned}$$

The weights adjustments along each axis (Wx, Wy) are given as (0.5, 0.5). Then, for database image 5, the similarity S = 0.5*0.9231+0.5*1.0 = 0.9616.

Rotation and Reflection of an Image

The problems of rotating an image (90, 180, 270 degrees clockwise) or reflecting an image (in the *x*-axis or *y*-axis) are considered in 2-D String, 2D G-string, and 2D C-string. Similarity must be retrieved and evaluated eight times for an image. Thus, a proper transformation must be performed for a string in each dimension. Strings require a sophisticated formula to transform spatial operators, except when reversed (Li & Qu, 1998). Even though 2D B-string does not require cutting objects from an image, it still recalculates their ranks.

If an image is represented in the 2D Bε-string, then the similarity retrieval of rotation and reflection of an image becomes very easy. Before evaluation, the string is only reversed, if necessary. The meaning, a dummy object between two adjoining boundary symbols, is not varied as the image is rotated or reflected because the dummy object is not a spatial operator.

The u and v are assumed to be the boundary strings of an image in the *x*-axis and the *y*-axis, respectively. They have m and n symbols, respectively; that is, $u = \{u_1u_2 \ldots u_{m-1}u_m\}$, $v = \{v_1v_2 \ldots v_{n-1}v_n\}$. The reversed string $u^{-1} = \{u_mu_{m-1} \ldots u_2u_1\}$ is defined for u and $v^{-1} = \{v_nv_{n-1} \ldots v_2v_1\}$ for v (shown as Table 7) summarizes the checklist of 2D Bε-strings between the original image and the image following rotation and/or reflection.

IMPLEMENTATION

A visualized image retrieval system is implemented using the proposed approaches of the 2D Bε-string spatial representation model and the modified LCS similarity evaluation algorithm. The system is divided into four parts. The first part converts MBR coordinate data of the original image into a symbolic picture represented in the 2D Bε-string. Part II randomly generates images, and calls part I to build a symbolic picture database. Each image includes an arbitrary number of objects. Each object is randomly assigned a set of MBR coordinate data. Part III performs similarity retrieval and evaluation. The final part handles the layout of the query image and the user interface interaction. Figure 7 shows the system's architecture.

After the retrieval system is begun (Figure 8), the user can load an image database from storage (Figure 9 and Figure 10), and browse them individually (Figure 11 and Figure 12). The user may place some available icons on the work area of the query image. He then drags them to an appropriate location and scales them appropriately (Figure 13). He hits the 'Search' button after he completes the layout of these icons in the query

image. The system will transform the query image into a 2D Bε-string and compare it to the database images. The most similar image and its similarity information (Figure 14) are then displayed. Clicking on the '2D Bε-string' tab switches to the 2D Bε-string (Figure 15). The user may also browse less similar images (Figure 16).

FUTURE TRENDS

The 2D Bε-string simplifies the representation of spatial relationships and improves the efficiency of similarity retrieval over those of other 2-D String methodologies. Even so, further research is required.

When an object area in an image differs greatly from its MBR area, the similarity is not

Figure 7. System architecture

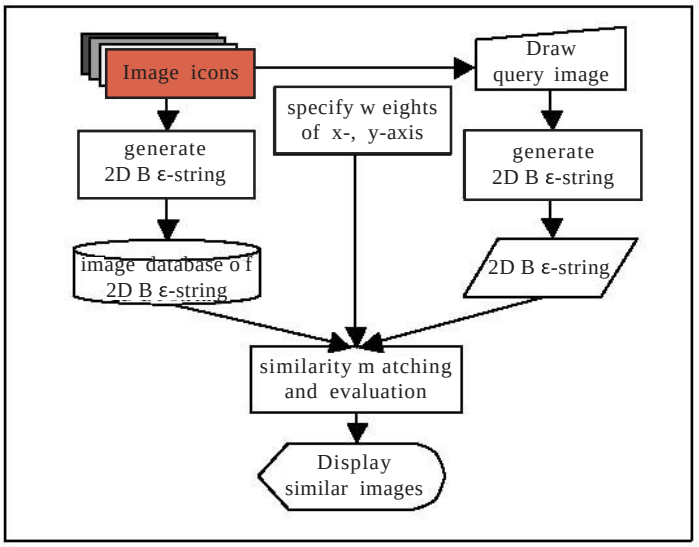

Figure 8. After the image retrieval system has loaded

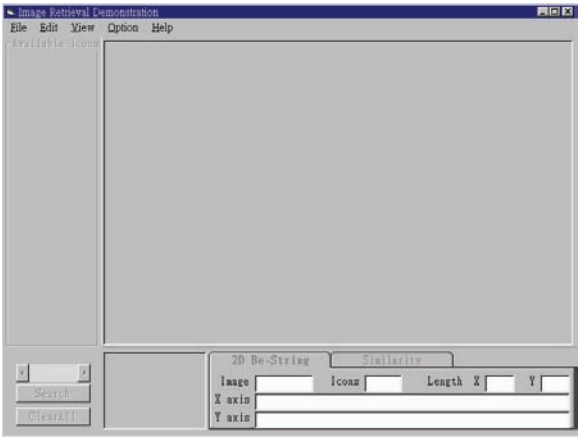

obvious, whether 2D Bε-string or other 2-D Strings are used. Human vision is such that the size of an object is considered to be one factor that determines similarity. However, 2D Bε-string and other 2-D Strings lose this information while abstracting. The distance between objects is also lost. Consequently, size and distance information in the 2D Bε-string representation model is worthy of further study.

Similarity can be more accurately evaluated than as evaluated here. The original LCS algorithm does not calculate the number of LCS paths, nor does the algorithm presented here. For evaluating similarity of a query image from different images in the database, even for LCS strings with the same length and content, more LCS paths correspond to greater similarity. Thus, modifying the presented similarity retrieval and evaluation approaches to

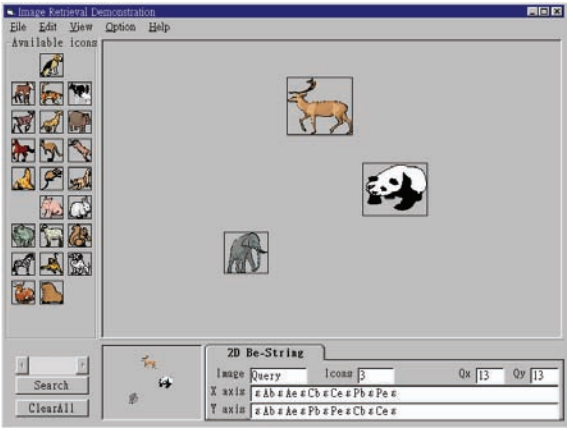

Figure 14. Most similar image and the similarity

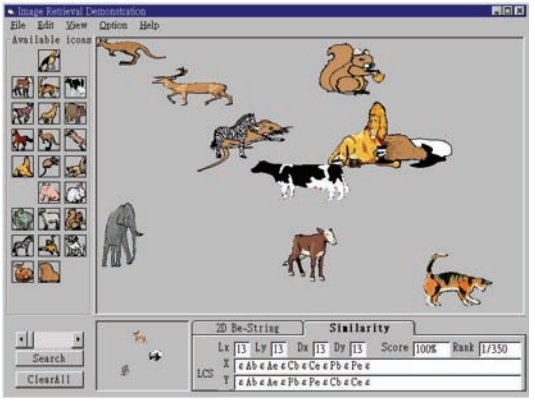

Figure 15. Most similar image and the 2D Be-string

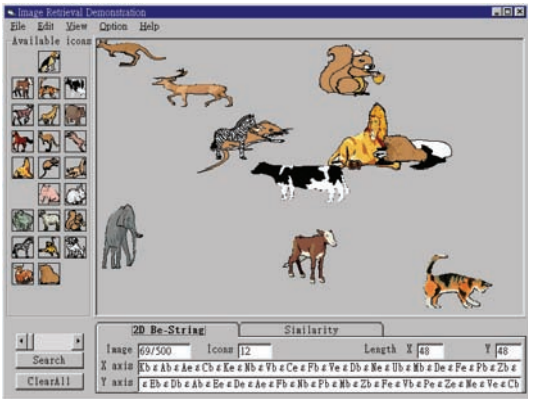

Figure 16. Next similar image and the similarity

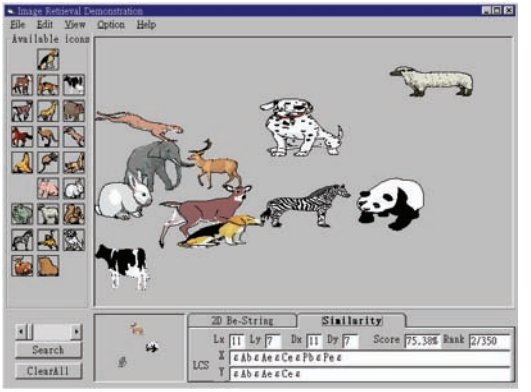

account for the number of LCS paths is an area of further study.

The 2D Bε-string representation model and similarity assessment can be easily expanded to retrieve objects in three-dimensions by directly adding the third dimension's string. For video data, adding extra temporal information as the third dimension allows a frame in a video to be indexed. The authors would also like to integrate the movement and velocity of objects in video images into the 2D Bε-string representation model in the near future.

CONCLUSION

This investigation proposes a spatial representation model, called the "2D Bε-string spatial representation" model. The model does not require an icon object to be cut from an image; but it rather represents an object by its MBR boundaries. The model depicts the spatial relationship between two boundary symbols by applying a 'dummy object.' It can, thus, intuitively represent the spatial relationship in an image. Additionally, the 2D Bε-string is directly formed from the object boundaries; thus, an image with n objects needs only between $2n$ and $4n+1$ storage units

in each dimension. The space complexity of 2D Bε-string is $O(n)$.

An algorithm, **Convert-2D-Bε-String**, is introduced to convert an image with MBR coordinate data into a symbolic image, represented in the 2D Bε-string. The space and time complexity of this algorithm is $O(n)$ when it does not consider the sort requirement.

A similarity retrieval algorithm, **2D-Bε-LCS-Length**, is also presented. It is modified from the LCS algorithm for use in the 2D Bε-string representation model. All the space and time complexities of the proposed algorithm are $O(mn)$, where m is the number of icon objects in the query image and n is the number of object icons in the image database.

Moreover, an evaluation process is elucidated, which can evaluate all similarities, regardless of how the LCS string is matched, whether all objects of the query image appear in the database image or whether all of the spatial relationships appear between the pair of images. In retrieving similarities of rotation and reflection, the approach need only to reverse the string and then apply the method of similarity retrieval and evaluation, mentioned above. This process does not require any conversion of spatial operators. It is more efficient and much easier than the previous methodologies.

Section 8

Emerging Trends

This section highlights research potential within the field of multimedia technologies while exploring uncharted areas of study for the advancement of the discipline. Introducing this section are selections addressing the need for universal access to multimedia. Additional selections discuss the future of multimedia education, advances in multimedia transmission on the Internet, and the possibilities and limitations of multimedia content protection. These contributions, which conclude this exhaustive, multi-volume set, provide emerging trends and suggestions for future research within this rapidly expanding discipline.

Chapter 8.1
Universal Multimedia Access

Andrea Cavallaro
Queen Mary, University of London, UK

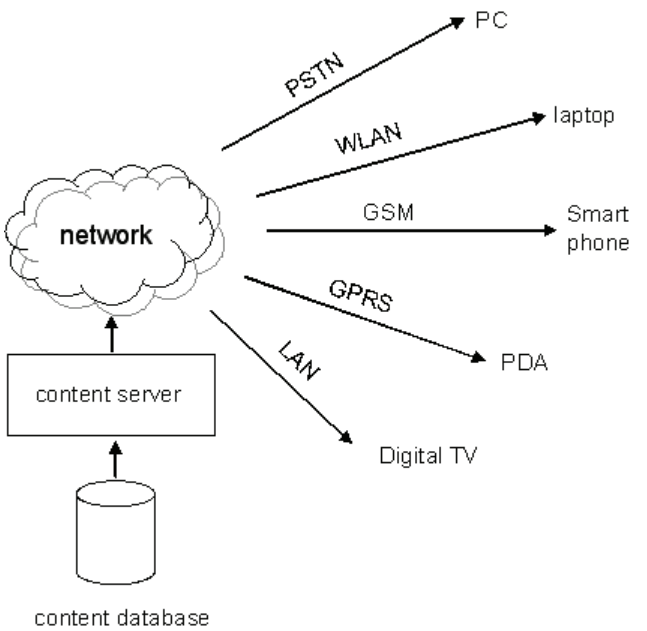
INTRODUCTION

The diffusion of network appliances such as cellular phones, personal digital assistants (PDAs), and handheld computers creates a new challenge for multimedia content delivery: how to adapt the media transmission to various device capabilities, network characteristics, and user preferences. Each device is characterized by certain display capabilities and processing power. Moreover, such appliances are connected through different types of networks with diverse bandwidths. Finally, users with different preferences access the same multimedia content. To cope with the challenge of delivering content to such a variety of conditions while maximizing user satisfaction, multimedia content needs to be adapted to the needs of the specific application, to the capabilities of the connected terminal and network, and to the preferences of the user (Mohan, Smith, & Li, 1999a; Van Beek, Smith, Ebrahimi, Suzuki, & Askelof, 2003). This adaptation enabling seamless access to multimedia content anywhere and anytime is known as universal multimedia access (UMA). The UMA framework is depicted in Figure 1. Three main strategies for adaptive multimedia content delivery have been proposed, namely, the info pyramid, scalable coding, and transcoding. These strategies, emerging trends in UMA and standardization activities, are discussed in the following sections.

INFO PYRAMID

Traditional solutions to multimedia adaptation encode and store multimedia content in a variety of modalities and formats that are expected to fit possible terminals and networks (Li, Mohan, & Smith, 1998). The most adequate version is then selected for delivery according to the network and hardware characteristics of the specific appliance. The advantage of this approach is speed of access because the content is already available and does not need to undergo any transformations. On the other hand, the limitation of this approach is the difficulty of generating a distinct content version for each profile of capabilities for the large variety of terminals and networks currently available. A general framework for managing and manipulat-

Figure 1. Universal multimedia-access framework (PSTN: Public Switched Telephone Network; WLAN: Wireless LAN; LAN: Local Area Network; GSM: Global System for Mobile Communications; GPRS: General Packet Radio Service)

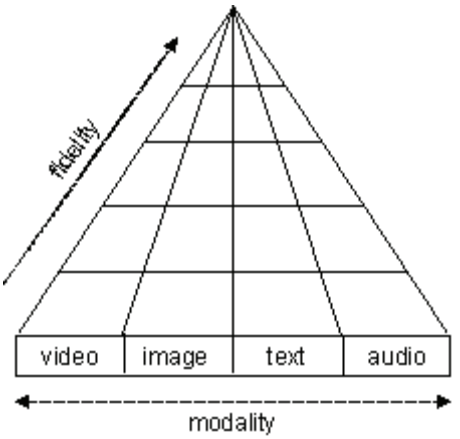


ing media objects is the info pyramid. The info pyramid manages different versions, or variations, of media objects with different modalities (e.g., video, image, text, and audio) and fidelities (summarized, compressed, and scaled variations). Moreover, it defines methods for manipulating, translating, transcoding, and generating the content (Smith, Mohan, & Li, 1999b). When a client device requests a multimedia document, the server selects and delivers the most appropriate variation. The selection is based on network characteristics and terminal capabilities, such as display size, frame rate, color depth, and storage capacity. The info pyramid of a media object is defined as a collection of the different variations of that media object, as shown in Figure 2. A content value score is then associated to each media object. The value score is assigned manually or based on some automatic measure, such as the entropy. Finally, the most appropriate media object is selected by maximizing the total content value for a set of device and/or network constraints. Utility-based frameworks are generally developed for the selection mechanism. In Mohan, Smith, and Li, (1999), the rate-distortion framework is generalized to a value-resource framework by treating different variations of a content item as different compressions, and different client resources as different bit rates. With the info pyramid approach, higher quality or higher resolution bit streams repeat the information already contained in lower quality or resolution streams. Then additional information is added to manage the streams. For these reasons, the info pyramid is not efficient. To overcome this problem, the redundancy should be removed by coding multiple fidelity levels into a single stream, as described in the next section.

SCALABLE CODING

As opposed to the info pyramid, scalable coding processes multimedia content only once. Lower qualities or lower resolutions of the same content

Figure 2. Multimodal representation of a media object as a collection of different variations of the same object in the info-pyramid approach

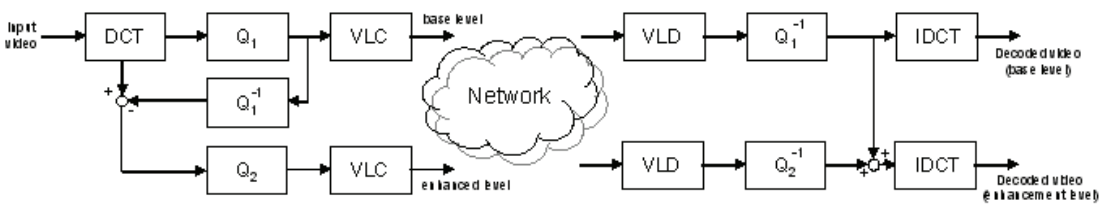


are then obtained by truncating certain layers or bits from the original stream (Wang, Osterman, & Zhang, 2002). In the case of video, basic modes of scalability include quality scalability, spatial scalability, temporal scalability, and frequency scalability. These basic scalability schemes can be combined to reach fine-granularity scalability, such as in MPEG-4 FGS (Fine Granularity Scalability) (Motion Pictures Expert Group; Li, 2001). Quality or SNR (Signal-to-Noise Radio) scalability is defined as the representation of a video sequence with varying accuracies in the color patterns. This is typically obtained by quantizing the color values with increasingly finer quantization step sizes, as shown in Figure 3. Spatial scalability is the representation of the same video in varying spatial resolutions. Corresponding layered bit streams are usually produced by computing a multiresolution decomposition of the original image. Next, the lowest resolution image is coded directly to produce a first layer. For each successive layer, the image from the previous layer is first interpolated to the new resolution, and then the error between the original and the interpolated image is encoded. Temporal scalability is the representation of the same video at varying temporal resolutions or frame rates. The procedure for producing temporally layered bit streams is similar to the procedure used for spatial scalability, but temporal resampling is used instead of spatial resampling. Frequency scalability includes different frequency components in each layer, with the base layer containing low-frequency components and the other layers containing increasingly high-frequency components. Such decomposition can be achieved via frequency transforms like the DCT (Discrete Cosine Transform) or wavelet transforms.

TRANSCODING

Transcoding is the process of converting a compressed multimedia signal into another compressed signal with different properties (Vetro, Christopoulos, & Sun, 2003). Unlike the info pyramid and scalable coding, transcoding can operate according to the current usage environment on the fly without requiring a priori

Figure 3. Flow diagram of an SNR scalable coder based on two levels. Q1, Q2: quantization (Q2 is finer than Q1), VLC: variable-length coder (IDCT: inverse discrete cosin transform)



knowledge of terminal and network capabilities. Early solutions to transcoding determined the output format based on network and appliance constraints only, independent of the semantics in the content. These solutions are referred to as content-blind transcoding techniques. Content-blind transcoding strategies include spatial resolution reduction, temporal resolution reduction, and bit-rate reduction (Vetro et al.). Spatial resolution reduction affects the size of each frame, thus enabling content distribution to devices with limited display capabilities. Spatial resolution reduction can be obtained by first decoding the video stream and then fully reencoding the reconstructed signal at the new resolution. This approach, referred to as cascaded pixel-domain transcoder, has high memory requirements and is computationally expensive. For this reason, spatial resolution reduction is mostly performed in the frequency domain using motion vector mapping and DCT-domain down-conversion techniques (Shanableh & Ghanbari, 2000; Tan, Liang, & Sun, 2004; Vetro, Hata, Kuwahara, Kalva, & Sekiguchi, 2002). Temporal resolution reduction modifies the frame rate to enable content distribution to devices with limited processing power. Frame-rate reduction is acceptable only when motion activity in the video is limited. When motion activity is high, temporal conversion may limit the impression of motion continuity for the user, thus sensibly reducing the perceived quality. Bit-rate reduction aims at meeting an available channel capacity. As for spatial and temporal resolution reduction, significant complexity savings can be achieved by using simplified frequency-domain architectures. For instance, drift-free MPEG-2-video bit-rate reduction can be performed entirely in the frequency domain by implementing the various modes of motion compensation defined by MPEG-2 in the DCT domain (Assuncao & Ghanbari, 1998). The transcoding strategies described thus far, referred to as intramedia transcoding strategies, do not change the media nature of the input signal. On the other hand, intermedia transcoding (or transmoding) is the process of converting the media input into another media format. Examples of intermedia transcoding include speech-to-text (Morgan & Bourlard, 1995) and video-to-text (Jung, Kim, & Jain, 2004) translation.

SEMANTIC ADAPTATION

The success of UMA applications depends on user satisfaction, which in turn depends on the perceived quality of the content delivered. In order to maximize the perceived video quality, an increasing research effort is aimed at improving coders by taking into account human factors (Lu, Lin, Yang, Ong, & Yao, 2004). The various adaptation methods introduced in the previous sections treat the entire scene uniformly, assuming that people may look at every pixel of the video. In reality, humans do not scan a scene in raster fashion. Our visual attention tends to jump from one point to another. These jumps are called saccades. The saccadic patterns depend on the visual scene as well as on the cognitive task to be performed. For this reason, recent adaptation techniques make use of semantics to minimize the degradation of important image regions (Cavallaro, Steiger, & Ebrahimi, 2003). These techniques attempt to emulate the human visual system to prioritize the visual data in order to improve the performance of the coders. To this end, a scene may be decomposed into objects (Cavallaro, Steiger, & Ebrahimi, 2002) as shown in Figure 4. Then, using object-based temporal scalability (OTS), the frame rate of foreground objects is enhanced so that the foreground has a smoother motion than the background. This is usually achieved by encoding the original video sequence at a low frame rate in a base layer. One or more enhancement layers representing only foreground objects are then encoded so as to achieve a higher frame rate than the base layer. Enhancement frames are coded by predicting from the base layer, followed by overlapping the objects

Figure 4. Automatic decomposition of a scene into background and foreground objects. This decomposition enables semantic adaptation with the separate processing of relevant and less relevant visual information.

of the enhancement layer on the combined frame. In semantic transcoding, optimal quantization parameters and frame skip can be determined for each video object individually (Vetro, Sun, & Wang, 2001). The bit-rate budget for each object is allocated by a difficulty hint, a weight indicating the relative encoding complexity of each object. Frame skip is controlled by a shape hint, which measures the difference between two consecutive shapes to determine whether an object can be temporally down-sampled without visible composition problems. Key objects are selected based on motion activity and bit complexity. Motion activity and spatial activity descriptors are used as well to combine the requantization of DCT coefficients with spatial down-sampling and temporal down-sampling for content-based, hybrid video transcoding (Liang & Tan, 2001).

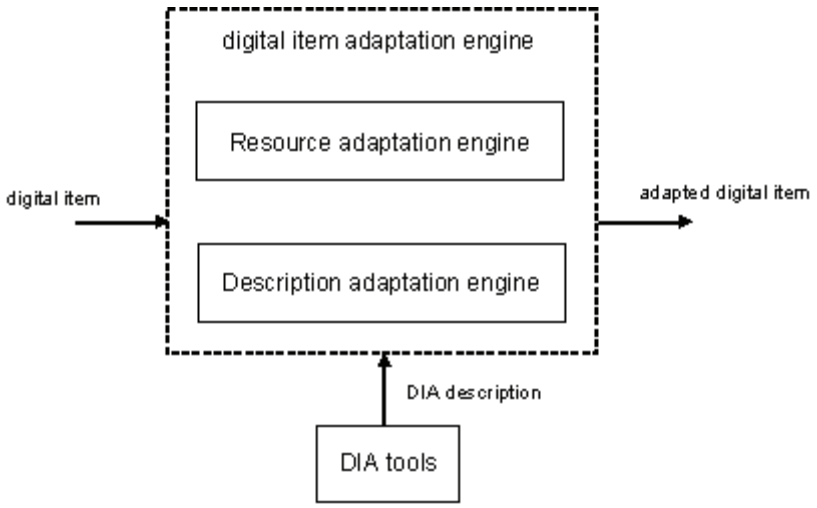
An important open issue in semantic adaptation is quality assessment. Perceptual quality assessment is a difficult task already when dealing with traditional coders such as MPEG-1 and MPEG-2 (Olsson, Stroppiana, & Baina, 1997). When dealing with semantic adaptation and user preferences, the task becomes even more challenging. For this reason, a combination of subjective and objective evaluation techniques is usually employed to compare the performance of different adaptation modalities. Traditional PSNR (Personal Signal-to-Noise Ration) analysis uniformly weighs the contribution of each pixel in an image when computing the mean squared error (MSE). Using this analysis, relevant as well as less relevant parts of an image are given the same importance. To account for the way humans perceive visual information, different parts of an image, or object classes, should be considered (Cucchiara, Grana, & Prati, 2002). Object classes are taken into account through a distortion measure, the semantic mean squared error, which assigns a different weight to each semantic class.

STANDARDS

Enabling access to any multimedia content from any type of terminal or network requires the definition and use of standard tools. In order to achieve interoperable and transparent access to multimedia content, the MPEG standardization committee developed MPEG-21, part 7 (MPEG MDS Group, 2003), which is focused on digital item adaptation (DIA). DIA (Vetro, 2004) aims at providing a set of standardized tools for the adaptation of digital items (Figure 5).

These tools enable the description of the usage environment. This description is based on information about terminal capabilities, network characteristics, user characteristics, and natural

Figure 5. MPEG-21 digital item adaptation architecture



environment characteristics. Terminal capabilities include information on device properties and codec capabilities. Device properties are storage and data I/O (input/output) characteristics, and power-related attributes. Codec capabilities specify the format that a terminal is capable of decoding. Network characteristics include network capabilities and network conditions. Network capabilities define the network's static attributes (e.g., minimum guaranteed bandwidth and maximum capacity), whereas network conditions describe dynamic network parameters, such as delay characteristics, available bandwidth, and error. User characteristics include usage history and user preferences, demonstration preference, accessibility characteristics, and location characteristics. Finally, natural environment characteristics pertain to the physical environmental conditions around the user that affect the way the content is consumed. Noise level and lighting conditions are examples of these characteristics. In addition to the above, natural environment characteristics represent time and location. MPEG-21 DIA specifies only the tools that assist with the adaptation process and not the adaptation engine itself, which is left outside the standard to enable the use of new and improved algorithms.

CONCLUSION

In this article, we discussed the concept of multimedia content delivery anywhere and anytime. In particular, we reviewed different forms for implementing UMA, namely, the info pyramid, scalable coding, and transcoding, and we discussed new adaptation forms based on content semantics. The info pyramid and scalable coding operate when the content is prepared. Content preparation aims at matching possible network and terminal capabilities. For this reason, potential profiles of capabilities need to be known a priori. On the other hand, transcoding takes place at the time of delivery. The input bit stream is converted according to the actual needs of the connected appliance and no prior knowledge is required. However, this flexibility comes at the price of a higher computational load. An emerging trend in UMA is the use of semantics that are being introduced in the adaptation mechanism in order to exploit the characteristics of human perception and maximize user experience.

Because accessing multimedia information anywhere and anytime enables an increase in productivity as well as the improvement of user satisfaction through new multimedia services

and applications, UMA is having a significant impact on large communities, from corporate to private users.

KEY TERMS

Info Pyramid: Multimedia data representation based on storing different versions of media objects with different modalities and fidelities.

Intermedia Transcoding: The process of converting the media input into another media format.

Intramedia Transcoding: A transcoding process that does not change the media nature of the input signal.

MPEG: Motion Pictures Expert Group.

MPEG-1: Standard for the coding of moving pictures and associated audio for digital storage media at up to about 1.5 Mbit/s. MPEG-1 is the standard on which video CD and MP3 are based.

MPEG-2: Standard for the generic coding of moving pictures and associated audio information. MPEG-2 is the standard on which digital television set-top boxes and DVD are based.

MPEG-4: Standard for multimedia for fixed and mobile Web.

MPEG-7: Multimedia content-description interface. MPEG-7 is the standard for the description and search of audio and visual content.

MPEG-21: Multimedia framework initiative that enables the transparent and augmented use of multimedia resources across a wide range of networks and devices.

Transcoding: The process of converting a compressed multimedia signal into another compressed signal with different properties.

UMA: Universal multimedia access.

Chapter 8.2
Towards a Taxonomy of Display Styles for Ubiquitous Multimedia

Florian Ledermann
Vienna University of Technology, Austria

Christian Breiteneder
Vienna University of Technology, Austria

ABSTRACT

In this chapter, a domain independent taxonomy of sign functions rooted in an analysis of physical signs found in public space is presented. This knowledge is necessary for the construction of future multimedia systems that are capable of automatically generating complex yet legible graphical responses from an underlying abstract information space such as a semantic network. The authors take the presence of a sign in the real world as indication for a demand for the information encoded in that sign, and identify the fundamental types of information that are needed to fulfill various tasks. For the information types listed in the taxonomy, strategies for rendering the information to the user in digital mobile multimedia systems are discussed.

INTRODUCTION

Future mobile and ubiquitous multimedia systems will be even more an integrated part of our everyday reality than it is the case today. A digital layer of information will be available in everyday situations and tasks, displayed on mobile devices, blended with existing contents of the real, physical world. Such an "augmented reality" (Azuma et al., 2001) will put into practice recent developments in the area of mobile devices, wireless networking, and ubiquitous information spaces, to be able to provide the right information to the right person at the right time.

The envisioned applications for these kinds of systems are manifold; the scenarios we are thinking of are based on a dense, spatially distributed information space which can be browsed by the user either explicitly (by using

navigation interfaces provided by hardware or software) or implicitly (by moving through space or changing one's intentions, triggering changes in the application's model of the user's *context*). Examples for the information stored in such an information space would be historical anecdotes, routes, and wayfinding information for a tourist guide or road and building information for wayfinding applications. The question of how to encode this information in a suitable and universal way is the subject of ongoing research in the area of semantic modeling (Chen, Perich, Finin, & Joshi, 2004; Reitmayr & Schmalstieg, 2005). For the applications we envision, we will require the information space not only to carry suitable abstract metainformation, but also multimedia content in various forms (images, videos, 3D-models, text, sound) that can be rendered to the user on demand.

Besides solving the remaining technical problems of storage, querying, distribution, and display of that information, which are the subject of some of the other chapters in this book, we have to investigate the consequences of such an omnipresent, ubiquitous computing scenario for the user interfaces of future multimedia applications. Up to now, most research applications have been mainly prototypes targeted towards a specific technical problem or use case; commercial applications mostly focus on and present an interface optimized for a single task (for example, wayfinding). In the mobile and ubiquitous multimedia applications we envision, the user's task and therefore the information that should be displayed cannot be determined in advance, but will be inferred at runtime from various aspects of the user's spatio-temporal context, selecting information and media content from the underlying information space dynamically. To communicate relevant data to the user, determined by her profile, task, and spatio-temporal context, we have to create legible representations of the abstract data retrieved from the information space. A fundamental problem here is that little applicable systematic knowledge exists about the automatic generation of graphical representations of abstract information.

If we want to take the opportunity and clarify rather than obscure by adding another layer of information, the following questions arise: Can we find ways to render the vast amounts of abstract data potentially available in an understandable, meaningful way, without the possibility of designing each possible response or state of such a system individually? Can we replace a part of existing signs in the real world, already leading to "semiotic pollution" (Posner & Schmauks, 1998) in today's cities, with adaptive displays that deliver the information the user needs or might want to have? Can we create systems that will work across a broad range of users, diverse in age, gender, cultural and socio-economical background?

A first step towards versatile systems that can display a broad range of context-sensitive information is to get an overview of which types of information could possibly be communicated. Up to now, researchers focused on single aspects of applications and user interfaces, as for example navigation, but to our knowledge there is no comprehensive overview of what kinds of information can generally occur in mobile information systems. In this article, we present a study that yields such an overview. This overview results in a *taxonomy* that can be used in various ways:

- It can be formalized as a schema for implementing underlying databases or semantic networks
- It can be used by designers to create representative use case scenarios for mobile and ubiquitous multimedia applications
- It can be used by programmers implementing these systems as a list of possible requirements.
- It can be used to systematically search the literature and conduct further research to compile a catalog of display techniques that satisfy the information needs identified.

Such a catalog of techniques, taken from available literature and extended with our own ideas, is presented in the second part of the article

BACKGROUND

Augmented reality blends sensations of the real world with computer-generated output. Already in the early days of this research discipline, its potential to not only add to reality, but also subtract from ("diminished reality") (Mann & Fung, 2002) or change it ("mediated reality") has been recognized. Over the past years, we have created prototypes of mobile augmented reality systems that can be used to roam extensive indoor or outdoor environments. The form factor of these devices has evolved from early back-pack systems (Reitmayr & Schmalstieg, 2004), which prohibited usage over longer time periods or by inexperienced users, to recent PDA-based solutions (Wagner & Schmalstieg, 2003), providing us with a system that can be deployed on a larger scale to untrained and unsupervised users and carried around over an extended time span in an extended environment. Furthermore, on the PDA-class devices, classical and emerging multimedia content formats can be easily integrated, leading to hybrid applications that can make use of different media, matching the needs of the user.

One of our research applications is concerned with outdoor wayfinding in a city (Reitmayr & Schmalstieg, 2004). As can be seen in Figure 1, the augmented reality display provides additional information like directional arrows, a compass, and an indication of the desired target object. After experiments with early ad-hoc prototypes, it became clear that a structured approach to the design of the user interface would be necessary to make our system usable across a wide range of users and tasks. A kind of "toolbox" with different visualization styles is needed to visualize the information in the most suitable way. To design and implement such a toolbox, we need to have an overview of the information needs that might

Figure 1. Our outdoor augmented reality wayfinding system

Directional arrows, landmarks, a compass and location information are superimposed on the view of the real world

occur in our applications, and look for techniques that can successfully fulfill these needs in a flexible, context-dependent way.

Plenty of studies exist that evaluate different display techniques for augmented reality systems. However, we found that the majority of these studies present a novel technique and test the usability of the technique, and do not compare different alternatives for satisfying the same information need. Therefore, these studies were of little direct value for us because they didn't allow us to compare techniques against each other or to find the best technique for a given task. We had to focus on identifying and isolating the proposed techniques, and leave the comparison of techniques against each other for future work. In the future, we will implement some of the proposed techniques and conduct user studies and experiments to be able to compare the techniques to each other.

For conventional 2D diagrams, Chappel and Wilson (1993) present a comparison of different diagram types for various informational purposes. They present a table, listing different tasks (such as, for example, "judging accurate values" or "showing relationships") and for each task, they list the best diagram type according to available cognitive psychology literature. The diagrams discussed include only classical diagram types like pie chart, bar chart or graphs, while we need results in a similar form for recently developed display techniques that can be applied to mobile augmented reality systems.

Some research has been done on the generation of automatic layout for augmented reality displays. Lok and Feiner (2001) present a survey of different automated layout techniques, knowledge that is used by Bell, Feiner, and Höllerer (2001) to present a system for view management for augmented reality. The only information type they are using are labels attached to objects in the view of the user. Nevertheless, their techniques can be applied for controlling the overall layout of an application, once the individual rendering styles for different parts of the display have been chosen.

As the found literature in the field of human-computer-interaction and virtual reality does not answer our questions stated in the introduction, we have to look into other, more theoretical disciplines to find guidelines for the generation of appropriate graphical responses for our systems.

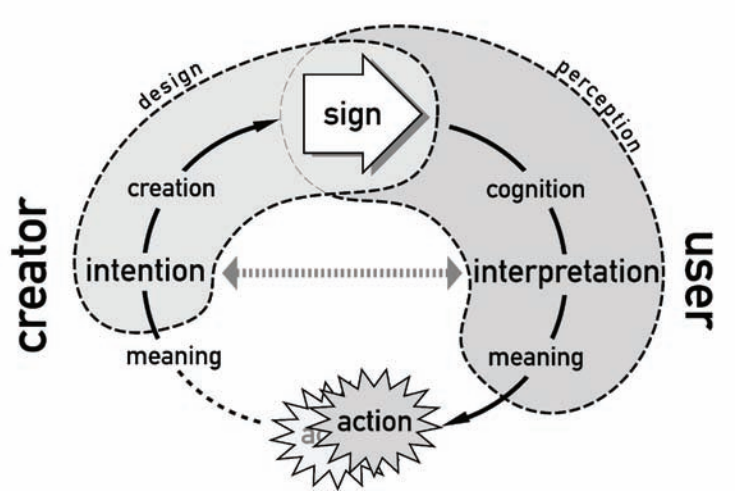
Semiotics and Design

The process that transforms the intention of some agent (software or human) into a legible sign that can be read and understood by users and possibly leads to some action on the user side involves a series of steps: creating a suitable graphical representation for the given intention, placing the created media artifact at a suitable location in the world, identification and perception of the sign by the user, interpreting the sign to extract some meaning and acting according to that meaning. Ideally, the original intention is preserved in this process, and the user acts exactly like the creator intended. However, in the real world these processes are complex, and understanding them is the subject of various scientific disciplines (Figure 2):

- Design theory (Norman, 1990) can teach us how to create aesthetically pleasing and legible signs
- Cognitive psychology (Goldstein, 2004) deals with the perceptual issues involved in sensing and reading
- Semiotics (Eco, 1976) is concerned with the transformation of observed facts into meaning

Generally, the research areas previously mentioned are usually concerned with far less dynamic information than present in the ubiquitous digital applications we are looking for. It is therefore not possible to directly implement the information systems we are envisioning based only on existing knowledge — we first have to examine how these aspects could play together

Figure 2. Sign creation and interpretation



in the context-sensitive applications we want to create. As a first step, we need an overview of what kinds of information can possibly be communicated through signs.

STUDYING REAL-WORLD SIGNS

How can we construct an overview of possible usages of a system we have not yet built? Our hypothesis is that fundamental information needs of our potential users are covered already in the world today, in the form of conventional media and signs. We undertook an exhaustive survey of signs and media artifacts in public space, and from that experience we extracted the core concepts or *atomic functions* of signs in the real world.

Our environments are full of signs—either explicitly and consciously created or left behind without intention. Examples for the first category would be road signs, signposts, labels, and door signs, but also stickers and graffitis, which use public surfaces as ground for articulation and discourse. The signs that are unconsciously created include traces of all kinds, like a path through the grass in a park or the garbage left behind after a barbecue, picnic, or rock concert. Also the design of an object or building can indicate some meaning or suggest some usage that is not explicitly encoded there, but presented as an affordance (Norman, 1990), a feature that is suggesting some way of usage in a more implicit way.

The starting point for our research are signs present in public space. We take existing signs and significant visual features of the environment as indicators for a demand for the information encoded in the sign and/or the individual or political will to create the sign. Therefore, the sign becomes the documentation of the action of its creation, and an indicator of possible actions that can be carried out by using the information that is encoded.

By collecting a large number of examples, we obtained an overview of sign usage in public space and were able to structure intentions and actions into categories, which we could analyze further and relate to each other. In the envisioned ubiquitous augmented reality applications, space and time will be fundamental aspects for structuring the presented information. We therefore focused on signs that are related to spatial or temporal aspects of the world—media created purely for information or the attraction of attention, without any reference to their location or temporal context

Figure 3. Some examples of images taken in our study: (a) annotated safety button; (b) number plate; (c) signposts; (d) roadsign; (e) graffiti; (f) map

(like, for example, advertisements) do not fall in this category.

The collection of examples has been gathered in the city of Vienna, Austria, in public space, public transport facilities, and some public buildings. The research was constrained to include only visual information, and most of the examples were originally photographed with a built-in mobile phone camera. This allowed the spontaneous gathering of new example images in everyday situations, and avoided the necessity to embark for specific "signspotting" trips, which would probably have biased the collection in some direction. Some of the images have been replaced by high-resolution images taken with a consumer digital camera on separate occasions; care has been taken to reproduce the original photo as closely as possible. An unstructured collection of example images is shown in Figure 3.

Obviously, the collection of examples is heavily biased by the photographer's view of the city, his routes, tasks, and knowledge. An improved approach would include several persons with different demographical backgrounds, especially age, cultural and professional background and of varying familiarity with the city. However, our study covers a good part of the explicit signs present in urban space, and allows us to draw conclusions that will be valuable for future research by us and others.

FUNDAMENTAL FUNCTIONS OF SIGNS

In this section, we give an overview of all atomic functions identified in our study. While it is impossible to prove that a given set of categories covers all possible examples without examining every single instance, these categories could already be successfully applied to a number of newly found examples. Therefore, there is some indication that the proposed set of functions covers at least a good part of the use cases that can be found in an urban, public space scenario.

We choose to arrange the functions in five fields, resembling what in our opinion are fundamental aspects of future context sensitive ubiquitous applications: Object metainformation, object relationship information, spatial information, temporal information, and communication. Inside the respective sections, the identified concepts are listed and discussed, together with possible display styles that can be used to render the information in multimedia information systems.

Object Metainformation

Adding metainformation to existing objects in the real world is a fundamental function of both real and digital information systems.

Naming

Naming establishes a linguistic reference for an object in a specific context. The user has to be part of that context to be able to correctly understand the name and identify the referenced object. The context also determines whether the name is unique or not—for example, the name of an institute is unique in the context of a university, but not in a global context. Depending on the user, displayed names have to be chosen appropriately to allow identification.

Identification

Identification is a more technical concept than naming, which allows identifying a specific entity, usually in a global context. Examples would be number plates for cars or street addresses for houses. Note that also in these examples, the identification might need additional parts in a larger context—in a city, the street name is usually unique, but not in a global context, where it has to be prefixed with country and municipality information.

Explanation

Explanation is important if it is not clear from an object's design how to use it, or if the user just wants it for informational purposes. Sometimes it is sufficient to name the object, if the name already implies the mode of operation. A special class of explanation that we identified is *type information*—information about what an object *is*. In contrast to naming, type information denotes the class of an object, and does not provide a reference to a specific instance. (Note that when only a single instance of an object is present in the current context, the type information might also be sufficient to identify the object. Example: "the door" in a room with only a single exit.)

As these three kinds of object-related information mentioned above are mostly textual, the primary problem for displaying it in a digital system is that of automatic layout. The placement, color, and size of labels have to be chosen to be legible, unobtrusive, and not conflicting with other elements of the display. Lok and Feiner (2001) examine different strategies of automatically

Figure 4. Examples for accentuated objects: (a) fire extinguisher; (b) first step of descending stairs; (c) important announcement in public transport system

generating appropriate layouts, knowledge which was used by Bell et al. (2001) to automatically place labels for objects in an augmented reality application.

Accentuation

Accentuation means to emphasize a specific object by increasing its visibility. In the real world, accentuation is mostly performed to permanently improve the visibility of objects or regions for safety reasons by using bright, high contrast colors. In digital systems, image-based methods like partially increasing the contrast or saturation could be used, as well as two- or three-dimensional rendering of overlay graphics. An approach found in some systems (Feiner, Macintyre, & Seligmann, 1993), however never formally evaluated against other techniques, is to superimpose a wireframe model of the object to be highlighted on the object — if the object in question is occluded by other things, dashed lines are used to indicate this. This approach is inspired by technical drawings, where dashed lines are often used to indicate invisible features.

Ownership

While ownership is actually relational information (to be discussed in the next section), linking an owner entity to a specific object, it can often be read as information about the purpose of an object. Examples are the logos of public transport companies on buses. In most cases, the user is not interested in a link to the location of the company, but reads the ownership information as an indication of the object's function.

General Metainformation

Metainformation is often found on device labels to indicate some key properties of the device. Obviously, in digital systems this information can be subject to sophisticated filtering, rendering only the relevant information according to the user's task context. For textual metainformation, the layout considerations discussed above apply.

Status

Display of an object's status is the most dynamic metainformation found in conventional signs—the current state of an object or a subsystem is displayed to the user by using LEDs or alphanumeric displays. In today's cities, this is used for example in public transport systems to display the time until arrival of the next bus.

Status information is, due to its dynamic nature, an example where conventional, physical signs are reaching their limitations. In digital information systems, the possibilities to include dynamic information are much greater. Appropriate filtering has to be applied to prevent information overload and provide only the necessary information to the user. For a discussion of information filtering in an augmented reality context, see Julier, Livingston, Brown, Baillot, and Swan (2000).

Object-Relationship Information

The second type of information we find in various contexts is relating objects to each other. Entities frequently related to each other are people, rooms, buildings, or locations on a map. In most cases, the location of both objects (and the user) determines how the relationship is displayed and what actions can be carried out by the user.

Linking

Linking an object in the real world with another entity is another often-found purpose of signs. In augmented reality applications, one of the two objects (or both) might be virtual objects placed at real world locations. For example, an object in the real world might be linked to a location on a map presented on the user's display.

Rendering a link to the user depends on how the user is supposed to use that information. If the user should be guided from the one object to the other one, arrows can be used to give directional information (see the section on wayfinding below). If the objects are related in some other way, it might be sensible to display the name, an image, or a symbolic representation of the second object, if available, and denote the type of relationship as suitable. If the two objects are close together and both are visible from the users point of view, a straight line can be rendered to connect the objects directly—an approach also used by Bell et al. (2001) to connect labels with the objects they are related to.

Browsing

Browsing means to give the user an overview of all entities that are available for a specific interaction. Real-world examples for browsing opportunities would be signs in the entrance areas of buildings that list all available rooms or persons. The user can choose from that list or look for the name of the entity she is trying to locate.

Computers are frequently used for browsing information. In contrast to the physical world, browsing can be combined with powerful information filtering that passes only relevant information to the user. In most cases, the system will be able to choose the relevant information from the user's context, making browsing only necessary when an explicit choice is to be made by the user.

Spatial Information

The term "navigation" is often used casually for some of the concepts in this section. In our research we found out, however, that we have to break this term down into subconcepts to get an insight into the real motivations and demands of users.

Wayfinding

Wayfinding is what is most often referred to as navigation—finding the way from the current location to a specific target object. Note that for wayfinding only, other aspects of the user's spatial context like overview or orientation can be ignored—the user could be guided by arrows, without having any mental representation of the space she is moving through. In real spaces, wayfinding is supported by arrows and signposts, labeled with the name of the destination object or area. In digital applications, a single, constantly displayed arrow can be used that changes direction as needed.

Overview

Overview supports the ability to build a mental model of the area and is useful for generic wayfinding — finding targets for which no explicit wayfinding information is available, or finding fuzzy targets like areas in a city or district. Also, overview is related to browsing, as it allows looking for new targets and previously unknown locations. Traditionally, overview has been supported by maps (Däßler, 2002). Digital maps offer several new possibilities, like the possibility to mark areas that have been visited by the user before (see the section on trails below).

Orientation

To be useful for wayfinding, overview has to be complemented by orientation, the ability of the user to locate herself on a map or in her mental model of the environment. Maps installed at fixed locations in the world can be augmented with static "You are here" markers, a feature that can be implemented in a dynamic way on a digital map (Vembar, 2004). Overview is also supported by *landmarks*, distinctive visual features of the environment that can be seen from many different

locations in the world. Ruddle (2001) points out the important role of landmarks in virtual environments, which often offer too few distinctive features with the consequence of users feeling lost or disoriented.

Marking Territories

Marking of districts or territories is another example for spatially related information. Real-world examples include road signs or marks on the ground marking the beginning and ending of certain zones (see Figure 5 for example images). One of the problems that conventional signs have is that a human needs to keep track of the current state of the zones she is in as she moves through space.

Spatial Awareness

Ideally, the beginning and ending markings are accompanied by information that provides continuous, ambient feedback of which zone the user is in. This can be found in some buildings, where different areas are marked by using differently colored marks on the walls. Obviously, in digital information systems there are more advanced ways to keep track of and visualize the zones a user is currently in. Continuous feedback, for example in the form of appropriate icons, can be provided to the user on her display, visualizing the currently active zones.

Remote Sensing

A new possibility that emerges with digital multimedia systems is that of remote sensing. By remote sensing, we mean the accessibility of a live video image or audio stream that can be accessed by the user from remote locations. Information provided by remote sensing is less abstract than the other discussed concepts, and opens up the possibility for the user's own interpretation. CCTV cameras installed in public space are an example of remote sensing, although the user group and technical accessibility are limited.

Traces

Traces are often created by crowd behavior and are indicators for usage or demands. Classical examples are paths through the grass in a park, indicating that the provided paths are not sufficient to fulfill the needs of the visitors. In the digital domain, traces can be much more dynamic, collected at each use of the system and annotated with metainformation like date or current task. Some research exists on how traces can be used to aid wayfinding and overview in large virtual environments (Grammenos, Filou, Papadakos, & Stephanidis, 2002; Ruddle, 2005).

Figure 5. Marking of zones: (a) beginning of a speed-limit zone; (b) dashed border surrounding a bus stop; (c) location awareness by colored marking on the wall

Temporal Information

An area where the limitations of conventional signs become clearly visible is information that changes over time. Temporal change has to be marked in advance if the validity of a sign changes over time (for example, parking limitations constrained only to specific times). This additional information can lead to cluttered and overloaded signs (see Figure 3(d)).

Temporal Marking

Temporal marking can be accomplished much easier in digital systems — if the sign is not valid, it can simply be hidden from the users view. Care has to be taken, however, that information that might be relevant for the user in the future (for example, the beginning of a parking limitation) is communicated in advance to allow the user to plan her actions. Which information is relevant to the user in these cases depends highly on the task and activity.

Temporary Change

Similarly, temporary change means the temporary change of a situation (for example, due to construction work) with an undefined ending date. In real world examples, it is usually clearly visible that the change is only temporary and the original state will be restored eventually. If we want to communicate a temporal change in a digital system, this aspect has to be taken into account.

Synchronization

Good examples for synchronization of different parties are traffic lights. Despite their simplicity, traffic lights are among the most complex dynamic information source that can be found in public space. Obviously, the capabilities of future multimedia systems to communicate dynamic information are much greater; therefore, synchronization tasks can probably be adapted dynamically to the current situation.

Sequencing

Synchronization is related to sequencing, where the user is guided through a series of steps to fulfill a task. In real world examples this is usually solved by providing a list of steps that the user is required to take. In digital systems, these steps can be displayed sequentially, advancing to the next step either by explicit user interaction or automatically, if the system can sense the completion of the previous step (for example, by sensing the user's location).

Communication

While signs are always artifacts of communication, signs in the real world are usually only created by legitimate authorities. There are few examples of direct user to user communication—a possibility that can be extended with digital information systems.

Articulation

The surfaces of a city enable articulation in the form of graffiti and posters. While mostly illegal, it is an important property of physical surfaces that they can be altered, extended, or even destroyed. Digital environments are usually much more constrained in what their users are able to do—the rules of the system are often directly mapped to the interaction possibilities that are offered to the user (not taking into account the possibility of hacking the system and bypassing the provided interaction mechanisms). If we replace physical signs by digital content, we should keep in mind that users may want to interact with the information provided, leaving marks, and comments for other users.

Discourse

Discourse through signs and writings involving two or more parties is much rarer observed in public space. The capabilities of networked information systems could improve the ability to support processes of negotiation and communication between multiple parties in public space.

Mapping the Taxonomy

As mentioned above, a linear representation of a taxonomy cannot reproduce a multi-dimensional arrangement of concepts and the relationships between them. To create a more intuitive overview, we have created a 2-dimensional map of the concepts of the taxonomy (Figure 6). Four of the main fields identified above (metainformation, spatial aspects, temporal aspects, communication) are represented in the corners of the map, and the individual concepts are arranged to represent their relation to these fields. In addition, related concepts are linked in the diagram.

RENDERING AND DISPLAY STYLES FOR MOBILE MULTIMEDIA

The following table summarizes the techniques that we identified for the various types of information from the taxonomy. The third column references appropriate literature, where the listed techniques have been discussed or evaluated. The table lists also tasks, for which no appropriate display technique has been presented or evaluated so far. These situations are opportunities for future work, to develop and evaluate techniques that are able to address the communication of the desired information.

CONCLUSION

To support the systematic design of future ubiquitous multimedia applications, we have provided an overview of the types of information that users may demand or content providers may want to communicate. We rooted that overview in a study of sign usage in the real world, taking

existing signs as indications for the demand for the information encoded in the sign. From that analysis, we can extrapolate the consequences of bringing that information into the digital domain, which will result in improved possibilities for the display of dynamic information, changing over time and with the context of the user.

While we could identify techniques for rendering some of the information types in digital systems, for some of the identified types of information further research is needed to identify appropriate ways of displaying them to the user. By identifying these "white spots" on our map of display techniques, we provide the basis for future research in the area, targeting exactly those areas where no optimal techniques have been identified so far.

The overview given by the taxonomy may be used by designers of future information systems as a basis for constructing more complex use cases, choosing from the presented scenarios the elements needed for the specific application context. In a (yet to be developed) more formalized way, the presented taxonomy can lay the ground for formal ontologies of tasks and information needs, which could result in more advanced, "semantic" information systems that are able to automatically choose filtering and presentation methods from the user's task and spatio-temporal context.

KEY TERMS

Augmented Reality: Augmented reality (AR) is a field of research in computer science which tries to blend sensations of the real world with computer-generated content. While most AR applications use computer graphics as their primary output, they are not constrained by definition to visual output—audible or tangible representations could also be used. A widely accepted set of requirements of AR applications is given by Azuma (2001):

- AR applications combine sensations of the real world with virtual content.
- AR applications are interactive in real-time
- AR applications are registered in the 3-dimensional space of the real world

Recently, several *mobile* AR systems have been realized as research prototypes, using laptop computers or handheld devices as mobile processing units.

Taxonomy: A taxonomy is a classification of things or concepts, often in a hierarchical manner.

Ubiquitous Computing: The term ubiquitous computing (UbiComp) captures the idea of integrating computers into the environment rather than treating them as distinct objects, which should result in more "natural" forms of interaction with a "smart" environment than current, screen-based user interfaces.

Chapter 8.3
Adaptation and Personalization of Web-Based Multimedia Content

Panagiotis Germanakos
National & Kapodistrian University of Athens, Greece

Constantinos Mourlas
National & Kapodistrian University of Athens, Greece

ABSTRACT

A traditional multimedia system presents the same static content and suggests the same next page to all users, even though they might have widely differing knowledge of the subject. Such a system suffers from an inability to be all things to all people, especially when the user population is relatively diverse. The rapid growth of mobile and wireless communication allowed service providers to develop new ways of interactions, enabling users to become accustomed to new means of multimedia-based service consumption in an anytime, anywhere, and anyhow manner. This chapter investigates the new multi-channel constraints and opportunities emerged by these technologies, as well as the new user-demanding requirements that arise. It further examines the relationship between the adaptation and personalization research considerations, and proposes a three-layer architecture for adaptation and personalization of Web-based multimedia content based on the "new" user profile, with visual, emotional, and cognitive processing parameters incorporated.

INTRODUCTION

Since 1994, the Internet has emerged as a fundamental information and communication medium that has generated extensive enthusiasm. The Internet has been adopted by the mass market more quickly than any other technology over the past century, and is currently providing an electronic connection between progressive entities and millions of users whose age, education, occupation, interest, and income demographics are excellent for sales or multimedia-based service provision.

The explosive growth in the size and use of the World Wide Web, as well as the complicated nature of most Web structures, may lead in orientation difficulties, as users often lose sight of the goal of their inquiry, look for stimulating rather than informative material, or even use the navigational features unwisely. To alleviate such navigational difficulties, researchers have put huge amounts of effort to identify the peculiarities of each user group, and design methodologies and systems that could deliver an adapted and personalized Web-content. To this date, there has not been a concrete definition of personalization. However, the many solutions offering personalization features meet an abstract common goal: to provide users with what they want or need without expecting them to ask for it explicitly (Mulvenna, Anand, & Buchner, 2000). A complete definition of personalization should include parameters and contexts such as user intellectuality, mental capabilities, socio-psychological factors, emotional states, and attention- grabbing strategies, since these could affect the apt collection of users' customization requirements, offering in return the best adaptive environments to the user preferences and demands.

With the emergence of wireless and mobile technologies, new communication platforms and devices, apart from PC-based Internet access, are now emerging, making the delivery of content available through a variety of media. Inevitably, this increases user requirements which are now focused upon an "*anytime, anywhere, and anyhow*" basis. Nowadays, researchers and practitioners not only have to deal with the challenges of adapting to the heterogeneous user needs and user environment issues such as current location and time (Panayiotou & Samaras, 2004), but they also have to face numerous considerations with respect to multi-channel delivery of the applications concerning multimedia, services, entertainment, commerce, and so forth. To this end, personalization techniques exploit Artificial Intelligence, agent-based, and real-time paradigms to give presentation and navigation solutions to the growing user demands and preferences.

This chapter places emphasis on the adaptation of the Web-based multimedia content delivery, starting with an extensive reference to the mobility and wireless emergence that sub-serves the rapid development of the multi-channel multimedia content delivery, and the peculiarities of the user profiling that significantly vary from the desktop to the mobile user. Furthermore, it approaches the existing adaptation (adaptive hypermedia) and personalization (Web personalization) techniques and paradigms that could work together in a coherent and cohesive way, since they are sharing the same goal, to provide the most apt result to the user. Lastly, having analyzed the aforementioned concepts, it defines a three-layer adaptation and personalization Web-based multimedia content architecture that is based on the introduction of a "new" user profile that incorporates user characteristics such as user perceptual preferences, on top of the "traditional" ones, and the semantic multimedia content that includes, amongst others, the perceptual provider characteristics.

MOBILITY EMERGENCE

The rapid development of the wireless and mobile advancements and infrastructures has evidently given "birth" to Mobile Internet. It is considered fundamental to place emphasis on its imperative existence, since statistics show that in the future the related channels will take over as the most sustainable mediums of Web-based (multimedia) content provision. Mobile Internet could be considered as a new kind of front-end access to Web-based content with specific capabilities of delivering on-demand real-time information. Nowadays, many sectors (governmental, private, educational, etc.) start to offer multimedia-based services and information via a variety of service delivery channels apart from the Web (Germanakos, Samaras, & Christodoulou, 2005). Two of

these mobile multimedia-based service delivery channels are mobile telephony and PDAs. These channels become more important considering the much faster growth of the mobile penetration rate compared to desktop-based Internet access. The most significant future development will be the growth of mobile broadband multimedia-based services, once the potential of third generation mobile (3G) and its enhancements, as well other wireless technologies, including W4, RLAN, satellite, and others, is realized. The dissemination of these technologies represents a paradigm shift that enables the emergence of new data multimedia-based services, combining the benefits of broadband with mobility, delivered over high-speed mobile networks and platforms.

Multi-Channel Web-Based Content Delivery Characteristics

"To struggle against the amplification of the digital divide and therefore to think 'user interaction' whatever the age, income, education, experience, and the social condition of the citizen" (Europe's Information Society, 2004).

The specific theme above reveals exactly the need for user-centered multimedia-based service development and personalized content delivery. In many ways, the new technology provides greater opportunities for access. However, there are important problems in determining precisely what users want and need, and how to provide Web-based content in a user-friendly and effective way. User needs are always conditioned by what they already get, or imagine they can get. A channel can change the user perception of a multimedia application; when users have a free choice between different channels to access an application, they will choose the channel that realizes the highest relative value for them. However, separate development of different channels for a single multimedia content (multi-channel delivery) can lead to inconsistencies such as different data formats or interfaces. To overcome the drawbacks of multiple-channel content delivery, the different channels should be integrated and coordinated.

Since successful multimedia-based service delivery depends on a vast range of parameters, there is not a single formula to fit all situations. However, there have been reported particular steps (IDA, 2004) that could guide a provider throughout the channel selection process. Moreover, it should be mentioned that the suitability and usefulness of channels depends on a range of factors, out of which technology is only one element. Additional features that could affect the service channels assessment could be: directness, accessibility and inclusion, speed, security and privacy, and availability. To realize though their potential value, channels need also to be properly implemented and operated.

The design and implementation complexity is rising significantly with the many channels and their varying capabilities and limitations. Network issues include low bandwidth, unreliable connectivity, lack of processing power, limited interface of wireless devices, and user mobility. On the other hand, mobile devices issues include small size, limited processing power, limited memory and storage space, small screens, high latency, and restricted data entry.

Initial Personalization Challenges and Constraints

The needs of mobile users differ significantly from those of desktop users. Getting personalized information "*anytime, anywhere, and anyhow*" is not an easy task. Researchers and practitioners have to take into account new adaptivity axes, along which the personalized design of mobile Web-based content would be built. Such applications should be characterized by flexibility, accessibility, quality, and security in a ubiquitous interoperable manner. User interfaces must be friendlier enabling active involvement (information acquisition), giving the control to the user

(system controllability), providing easy means of navigation and orientation (navigation), tolerating users' errors, supporting system-based and context-oriented correction of users' errors, and finally enabling customization of multi-media and multi-modal user interfaces to particular user needs (De Bra, Aroyo, & Chepegin, 2004; De Bra & Nejdl, 2004). Intelligent techniques have to be implemented that will enable the development of an open Adaptive Mobile Web (De Bra & Nejdl, 2004), having as fundamental characteristics the directness, high connectivity speed, reliability, availability, context-awareness, broadband connection, interoperability, transparency and scalability, expandability, effectiveness, efficiency, personalization, security, and privacy (Lankhorst, Kranenburg, Salden, & Peddemors, 2002; Volokh, 2000).

PERSONALIZATION CONSIDERATIONS IN THE CONTEXT OF DESKTOP AND MOBILE USER

The science behind personalization has undergone tremendous changes in recent years while the basic goal of personalization systems was kept the same, to provide users with what they want or need without requiring them to ask for it explicitly. Personalization is the provision of tailored products, multimedia-based services, Web-based multimedia content, information, or information relating to products or services. Since it is a multi-dimensional and complicated area (covering also recommendation systems, customization, adaptive Web sites, Artificial Intelligence), a universal definition that would cover all its theoretical areas has not been given so far. Nevertheless, most of the definitions that have been given to personalization (Kim, 2002; Wang & Lin, 2002) are converging to the objective that is expressed on the basis of delivering to a group of individuals relevant information that is retrieved, transformed, and/or deduced from information sources in the format and layout as well as specified time intervals.

Comprehensive User Requirements and the Personalization Problem

The user population is not homogeneous, nor should be treated as such. To be able to deliver quality knowledge, systems should be tailored to the needs of individual users providing them personalized and adapted information based on their perceptions, reactions, and demands. Therefore, a serious analysis of user requirements has to be undertaken, documented, and examined, taking into consideration their multi-application to the various delivery channels and devices. Some of the user (customer) requirements and arguments anticipated could be clearly distinguished into Top of the Web (2003) and CAP Gemini Ernst & Young (2004): (a) General User Service Requirements (flexibility: anyhow, anytime, anywhere; accessibility; quality; and security), and (b) Requirements for a Friendly and Effective User Interaction (information acquisition; system controllability; navigation; versatility; errors handling; and personalization).

Although one-to-one multimedia-based service provision may be a functionality of the distant future, user segmentation is a very valuable step in the right direction. User segmentation means that the user population is subdivided, into more or less homogeneous, mutually-exclusive subsets of users who share common user profile characteristics. The subdivisions could be based on: demographic characteristics (i.e. age, gender, urban- or rural-based, region); socio-economic characteristics (i.e. income, class, sector, channel access); psychographic characteristics (i.e. life style, values, sensitivity to new trends); individual physical and psychological characteristics (i.e. disabilities, attitude, loyalty).

The issue of personalization is a complex one with many aspects and viewpoints that need to

be analyzed and resolved. Some of these issues become even more complicated once viewed from a moving user's perspective, in other words when constraints of mobile channels and devices are involved. Such issues include, but are not limited to: what content to present to the user, how to show the content to the user, how to ensure the user's privacy, how to create a global personalization scheme. As clearly viewed, user characteristics and needs, determining user segmentation, and thus provision of the adjustable information delivery, differ according to the circumstances and change over time (Panayiotou and Samaras, 2004).

There are many approaches to address these issues of personalization, but usually, each one is focused upon a specific area, that is, whether this is profile creation, machine learning and pattern matching, data and Web mining, or personalized navigation.

Beyond the "Traditional" User Profiling

One of the key technical issues in developing personalization applications is the problem of how to construct accurate and comprehensive profiles of individual users and how these can be used to identify a user and describe the user behavior, especially if they are moving (Adomavicious & Tuzhilin, 1999). According to Merriam-Webster dictionary, the term profile means "a representation of something in outline". User profile can be thought of as being a set of data representing the significant features of the user. Its objective is the creation of an information base that contains the preferences, characteristics, and activities of the user. A user profile can be built from a set of keywords that describe the user-preferred interest areas compared against information items.

User profiling is becoming more and more important with the introduction of the heterogeneous devices used, especially when published contents provide customized views on information. User profiling can either be static, when it contains information that rarely or never changes (e.g. demographic information), or dynamic, when the data change frequently. Such information is obtained either explicitly, using online registration forms and questionnaires resulting in static user profiles, or implicitly, by recording the navigational behavior and/or the preferences of each user. In the case of implicit acquisition of user data, each user can either be regarded as a member of a group and take up an aggregate user profile or be addressed individually and take up an individual user profile. The data used for constructing a user profile could be distinguished into: (a) the Data Model which could be classified into the demographic model (which describes who the user is), and the transactional model (which describes what the user does); and (b) the Profile Model which could be further classified into the factual profile (containing specific facts about the user derived from transactional data, including the demographic data, such as "the favorite beer of customer X is Beer A"), and the behavioral profile (modeling the behavior of the user using conjunctive rules, such as association or classification rules. The use of rules in profiles provides an intuitive, declarative, and modular way to describe user behavior (Adomavicious & Tuzhilin, 1999)). Additionally, in the case of a mobile user, by user needs is implied both the thematic preferences (i.e., the traditional notion of profile) as well as the characteristics of their personal device called "device profile". Therefore, here, adaptive personalization is concerned with the negotiation of user requirements and device abilities.

But, could the user profiling be considered complete incorporating only these dimensions? Do the designers and developers of multimedia-based services take into consideration the real user preferences in order to provide them a really personalized Web-based multimedia content? Many times this is not the case. How can user profiling be considered complete, and

the preferences derived optimized, if it does not contain parameters related to the user perceptual preference characteristics? We could define User Perceptual Preference Characteristics as all the critical factors that influence the visual, mental, and emotional processes liable of manipulating the newly received information and building upon prior knowledge, that is different for each user or user group. These characteristics determine the visual attention, cognitive, and emotional processing taking place throughout the whole process of accepting an object of perception (stimulus) until the comprehensive response to it. It has to be noted at this point that the user perceptual preference characteristics are directly related to the "traditional" user characteristics since they are affecting the way a user approaches an object of perception.

It is true that nowadays, there are not so many researches that move towards the consideration of user profiling to incorporate optimized parameters taken from the research areas of visual attention processing and cognitive psychology. Some serious attempts have been made on approaching e-learning systems providing adapted content to the students, but most of them are lying to restricted analysis and design methodologies considering particular cognitive learning styles, including Field Independence vs. Field Dependence, Holistic-Analytic, Sensory Preference, Hemispheric Preferences, and Kolb's Learning Style Model (Yuliang & Dean, 1999), applied to identified mental models, such as concept maps, semantic networks, frames, and schemata (Ayersman & Read, 1999). In order to deal with the diversified students' preferences, they are matching the instructional materials and teaching styles with the cognitive styles, and consequently they are satisfying the whole spectrum of the students' cognitive learning styles by offering a personalized Web-based educational content.

A COMPREHENSIVE OVERVIEW OF ADAPTATION AND PERSONALIZATION TECHNIQUES AND PARADIGMS: SIMILARITIES AND DIFFERENCES

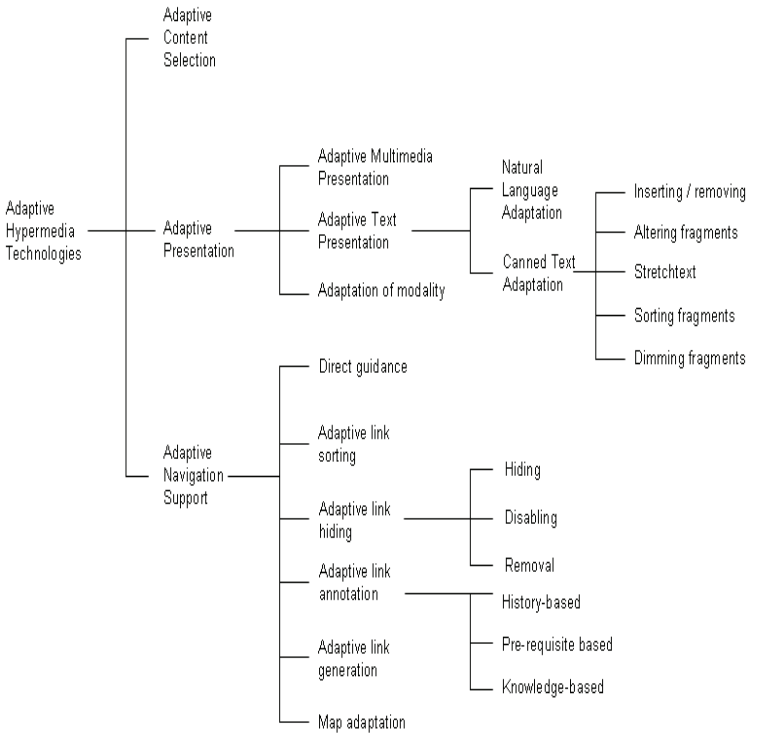
When we are considering adaptation and personalization categories and technologies, we refer to Adaptive Hypermedia and Web Personalization respectively, due to the fact that together these can offer the most optimized adapted content result to the user.

Adaptive Hypermedia Overview

Adaptive Hypermedia is a relatively old and well-established area of research counting three generations: The first "pre-Web" generation of adaptive hypermedia systems explored mainly adaptive presentation and adaptive navigation support and concentrated on modeling user knowledge and goals. The second "Web" generation extended the scope of adaptive hypermedia by exploring adaptive content selection and adaptive recommendation based on modeling user interests. The third "New Adaptive Web" generation moves adaptive hypermedia beyond traditional borders of desktop hypermedia systems embracing such modern Web trends as "mobile Web", "open Web", and "Semantic Web" (Brusilovsky & Maybury, 2002).

Adaptivity is a particular functionality that alleviates navigational difficulties by distinguishing between interactions of different users within the information space (De Bra & Nejdl, 2004; Eklund & Sinclair, 2000). Adaptive Hypermedia Systems employ adaptivity by manipulating the link structure or by altering the presentation of information, based on a basis of a dynamic understanding of the individual user, represented in an explicit user model (Brusilovsky, 1996; De Bra et al., 1999; Eklund, & Sinclair, 2000). In 1996, Brusilovsky identified four user characteristics to which an

Figure 1. Adaptive hypermedia techniques

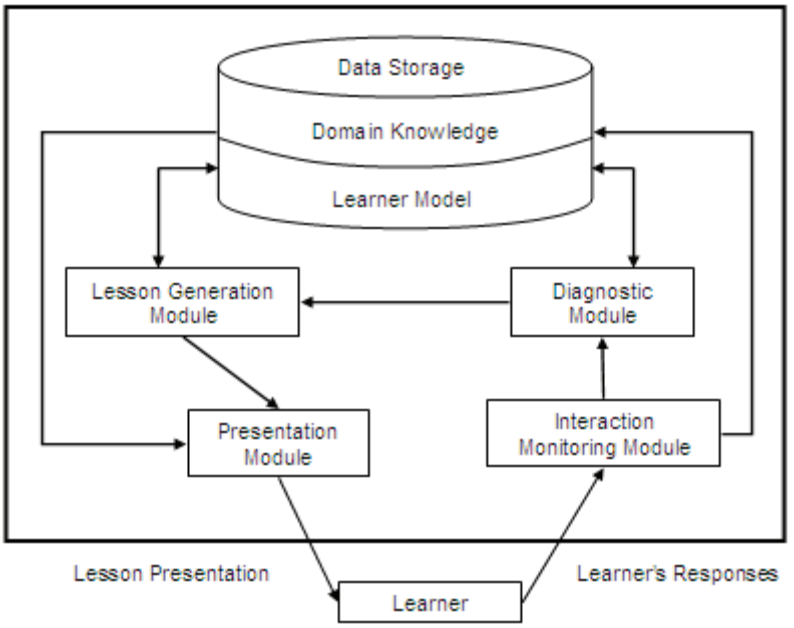


Adaptive Hypermedia System should adapt. These were: user's knowledge, goals, background and hypertext experience, and user's preferences. In 2001, further two sources of adaptation were added to this list, user's interests and individual traits, while a third source of different nature having to deal with the user's environment had also been identified.

Generally, Adaptive Hypermedia Systems can be useful in application areas where the hyperspace is reasonably large and the user population is relatively diverse in terms of the above user characteristics. A review by Brusilovsky has identified six specific application areas for adaptive hypermedia systems since 1996 (Brusilovsky, 2001). These are: educational hypermedia, online information systems, information retrieval systems, institutional hypermedia, and systems for managing personalized view in information spaces. Educational hypermedia and on-line information systems are the most popular, accounting for about two- thirds of the research efforts in adaptive hypermedia. Adaptation effects vary from one system to another. These effects are grouped into three major adaptation technologies: adaptive content selection (De Bra & Nejdl, 2004), adaptive presentation (or content-level adaptation), and adaptive navigation support (or link-level adaptation) (Brusilovsky, 2001; De Bra et al., 1999; Eklund & Sinclair, 2000) and are summarized in Figure 1.

As mentioned earlier, successful adaptation attempts have been made in the e-learning research field to provide the students with adapted content according to their different learning styles or knowledge level and goals. A typical case of such a system could be considered the INSPIRE (Intelligent System for Personalized Instruction in a Remote Environment) architecture, see Figure 2, where throughout its interaction with the

Figure 2. INSPIRE's components and the interaction with the learner



learner, the system dynamically generates lessons that gradually lead to the accomplishment of the learning goals selected by the learner (Papanikolaou, Grigoriadou, Kornilakis, & Magoulas, 2002). INSPSIRE architecture has been designed so as to facilitate knowledge communication between the learner and the system and to support its adaptive functionality.

INSPIRE comprises of five different modules: (a) the *Interaction Monitoring Module* that monitors and handles learner's responses during his/her interaction with the system, (b) the *Learner's Diagnostic Module* that processes data recorded about the learner and decides on how to classify the learner's knowledge, (c) the *Lesson Generation Module* that generates the lesson contents according to learner's knowledge goals and knowledge level, (d) the *Presentation Module* which functions to generate the educational material pages sent to the learner, and (e) the *Data Storage*, which holds the *Domain knowledge* and the *Learner's Model.*

Web Personalization Overview

Web Personalization refers to the whole process of collecting, classifying, and analyzing Web data, and determining based on these the actions that should be performed so that the information is presented in a personalized manner to the user. As inferred from its name, Web Personalization refers to Web applications solely (with popular use in e-business multimedia-based services), and generally is a relatively new area of research. Web personalization is the process of customizing the content and structure of a Web site to the specific needs of each user by taking advantage of the user's navigational behavior. Being a multi-dimensional and complicated area, a universal definition has not been agreed to date. Nevertheless, most of the definitions given to Web personalization (Cingil, Dogac, & Azgin, 2000; Kim, 2002) agree that the steps of the Web personalization process include: (1) the collection of Web data, (2) the modeling and categorization of these data (pre-processing phase), (3) the analysis of the collected data, and

the determination of the actions that should be performed. Moreover, many argue that emotional or mental needs, caused by external influences, should also be taken into account.

Web Personalization could be realized in one of two ways: (a) Web sites that require users to register and provide information about their interests, and (b) Web sites that only require the registration of users so that they can be identified (De Bra et al., 2004). The main motivation points for personalization can be divided into those that are primarily to facilitate the work, and those that are primarily to accommodate social requirements. The former motivational subcategory contains the categories of enabling access to information content, accommodating work goals, and accommodating individual differences, while the latter contains the categories of eliciting an emotional response and expressing identity.

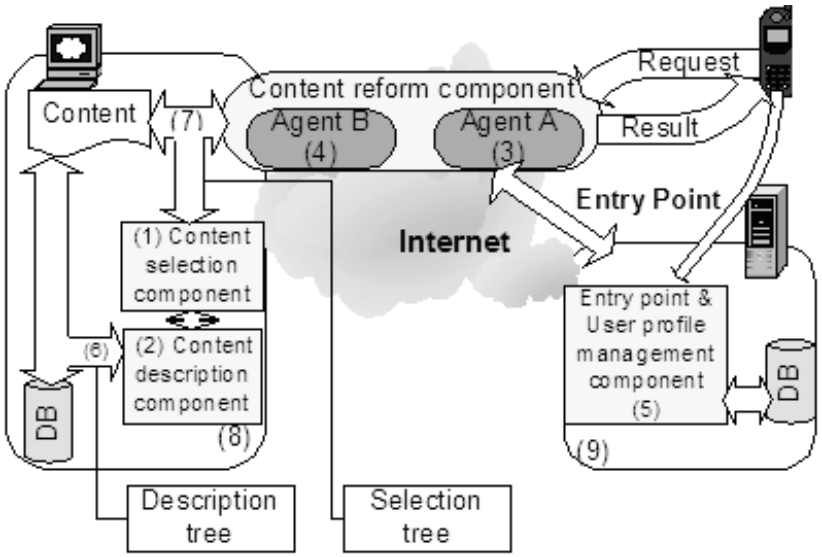
Personalization levels have been classified into: Link Personalization (involves selecting the links that are more relevant to the user, changing the original navigation space by reducing or improving the relationships between nodes), Content Personalization (user interface can present different information for different users providing substantive information in a node, other than link anchors), Context Personalization (the same information (node) can be reached in different situations), Authorized Personalization (different users have different roles and therefore they might have different access authorizations) and Humanized Personalization (involves human computer interaction) (Lankhorst et al., 2002; Rossi, Schwade, & Guimaraes, 2001). The technologies that are employed in order to implement the processing phases mentioned above as well as the Web personalization categories are distinguished into: Content-Based Filtering, Rule-Based Filtering, Collaborative Filtering, Web Usage Mining, Demographic-Based Filtering, Agent Technologies, and Cluster Models (Mobasher, 2002; Pazzani, 1999; Perkowitz & Etzioni, 2003).

The use of the user model is the most evident technical similarity of Adaptive Hypermedia and Web Personalization to achieve their goal. However, the way they maintain the user profile is different; Adaptive Hypermedia requires a continuous interaction with the user, while Web Personalization employs algorithms that continuously follow the users' navigational behavior without any explicit interaction with the user. Technically, two of the adaptation/personalization techniques used are the same. These are adaptive-navigation support (of Adaptive Hypermedia and else referred to as link-level adaptation) and Link Personalization (of Web Personalization) and adaptive presentation (of Adaptive Hypermedia and else referred to as content-level adaptation) and Content Personalization (of Web Personalization).

An example of a Web personalization application for the wireless user is the mPERSONA system, depicted in Figure 3. The mPERSONA system architecture combines existing techniques in a component-based fashion in order to provide a global personalization scheme for the wireless user. The mPERSONA is a flexible and scalable system that focuses towards the new era of wireless Internet and the moving user. The particular architecture uses autonomous and independent components avoiding this way tying up to specific wireless protocols (e.g., WAP). To achieve a high degree of independence and autonomy, mPERSONA is based on mobile agents and mobile computing models such as the "client intercept model" (Panayiotou & Samaras, 2004).

The architectural components are distinguished based on their location and functionality: a) the *Content description* component (Figure 3: 2 & 6), creates and maintains the content's provider metadata structure that describes the actual content, (b) the *Content selection* component (Figure 3: 1 & 7), selects the content that will be presented to the user when "applying" his profile, (c) the *Content reform* component (Figure 3: 3 & 4), reforms and delivers the desired content in the

Figure 3. Detailed view of the mPERSONA architecture



needed (by the user's device) form, and (d) the *User profile management* component (Figure 3: 5), registers and manages user profiles. The user's profile is split into two parts: the device profile (covers the user's devices) and the theme profile (preferences).

A THREE-LAYER ARCHITECTURE FOR ADAPTATION AND PERSONALIZATION OF WEB-BASED MULTIMEDIA CONTENT

Based on the above considerations, a three-layer architecture for adaptation and personalization of Web-based multimedia content will now be presented, trying to convey the essence and the peculiarities encapsulated, and further answering the question why adaptation and personalization of Web-based content is considered vital for the sustainable provision of quality multi-channel Web-based multimedia content/multimedia-based services.

The current architecture, depicted in Figure 4, Adaptation and Personalization of Web-based Multimedia Content Architecture, is composed of three interrelated parts/layers. Each *layer* for the purpose of the infrastructure functionality may be composed of *components*, and each component may be broken down into *elements*, as detailed below:

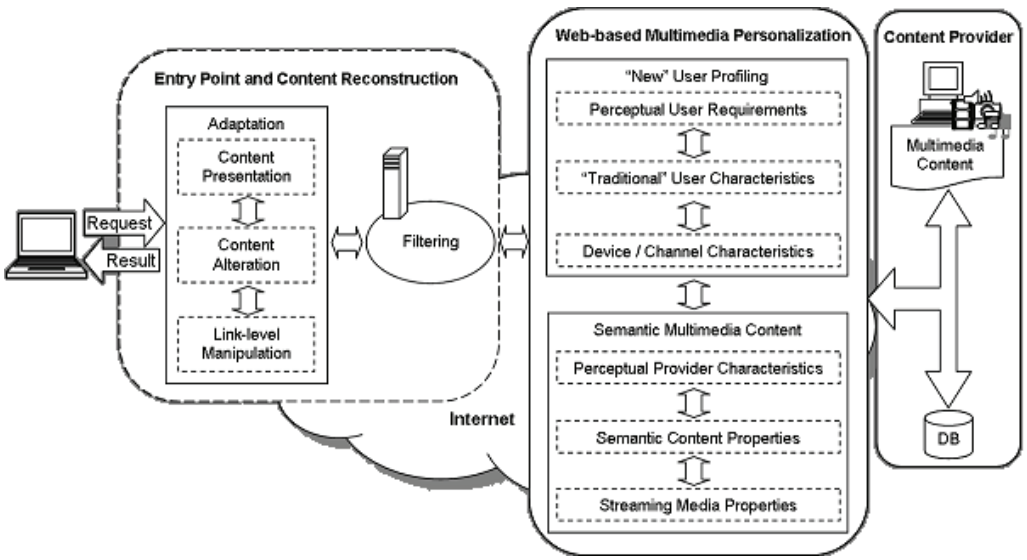
Front-End Layer (Entry Point and Content Reconstruction)

The front-end layer is the primary layer, and it is the user access interface of the system. It is called "Entry Point and Content Reconstruction", and it accepts multi-device requests. It enables the attachment of various devices on the infrastructure (such as mobile phones, PDAs, desktop devices, tablet PC, satellite handset, etc.) identifying their characteristics and preferences as well as the location of the user currently active (personalization/locationbased). It also handles multi-channel requests. Dut to the variety of multi-channel delivery (i.e., over the Web, telephone, interactive kiosks, WAP, MMS, SMS, satellite, and so on),

this layer identifies the different characteristics of the channels. It directly communicates with the middle layer exchanging multi-purpose data. It consists of two components, each one assigned for a different scope:

- **Adaptation:** This component comprises of all the access-control data (for security reasons) and all the information regarding the user profile. These might include user preferences, geographical data, device model, age, business type, native language, context, and so forth. It is the entry point for the user, enabling the login to the architecture. This component is directly communicating with the middle layer where the actual verification and profiling for the user is taking place. Once the whole processing has been completed, it returns the adapted results to the user. It is comprised of three elements:
  - **Content Presentation (or Adaptive Presentation):** It adapts the content of a page to the characteristics of the user according to the user profile and personalization processing. The content is individually generated or assembled from pieces for each user, to contain additional information, pre-requisite information, or comparative explanations by conditionally showing, hiding, highlighting, or dimming fragments on a page. The granularity may vary from word replacement to the substitution of pages to the application of different media.
  - **Content Alteration (or Adaptive Content Selection):** When the user searches for a particular content, that is, related information to his/her profile, the system can adaptively select and prioritize the most relevant items.
  - **Link-Level Manipulation (or Adaptive Navigation Support):** It provides methods that restrict the user's interactions with the content or techniques that aid the user in their understanding of the information space, aiming to provide either orientation or guidance (i.e. adaptive link, adaptive link hiding/an-

Figure 4. Adaptation and personalization of Web-based multimedia content architecture



notation). Orientation informs the user about his/her place in the information space, while guidance is related to a user's goal.

- **Filtering:** This component is considered the main link of the front-layer with the middle layer of the architecture. It actually transmits the data accumulated both directions. It is responsible for making the the low-level reconstruction and filtering of the content, based on the personalization rules created, and to deliver the content for adaptation.

Middle Layer (Web-Based Multimedia Personalization)

The middle layer is the main layer of the architecture and it is called "Web-Based Multimedia Personalization". At this level all the requests are processed. This layer is responsible for the custom tailoring of information to be delivered to the users, taking into consideration their habits and preferences, as well as, for mobile users mostly, their location ("location-based") and time ("time-based") of access. The whole processing varies from security, authentication, user segmentation, multimedia content identification, to provider perceptual characteristics, user perceptions (visual, mental and emotional), and so forth. This layer accepts requests from the front-end and, after the necessary processing, either sends information back or communicates with the next layer (back-end) accordingly. The middle layer is comprised of the following two components:

- **"New" User Profiling:** It contains all the information related to the user, necessary for the Web Personalization processing. It is directly related to the Semantic Multimedia Content component and is composed of three elements:
  - **Perceptual User Requirements:** This is the new element/dimension of the user profile. It contains all the visual attention and cognitive processes (cognitive and emotional processing parameters) that completes the user perception and fulfills the user profile. It is considered a vital element of the user profile since it identifies the aspects of the user that is very difficult to be revealed and measured but, however, might determine his/her exact preferences and lead to a more concrete, accurate, and optimized user segmentation.
  - **"Traditional" User Characteristics:** This element is directly related to the Perceptual User Requirements element and provides the so-called "traditional" characteristics of a user: knowledge, goals, background, experience, preferences, activities, demographic information (age, gender), socio-economic information (income, class, sector, etc.), and so forth. Both elements are completing the user profiling from the user's point of view.
  - **Device/Channel Characteristics:** This element is referring to all the characteristics that referred to the device or channel that the user is using and contains information like: bandwidth, displays, text-writing, connectivity, size, power processing, interface and data entry, memory and storage space, latency (high/low), and battery lifetime. These characteristics are mostly referred to mobile users and are considered important for the formulation of a more integrated user profile, since it determines the technical aspects of it.

- **Semantic Multimedia Content:** This component is based on metadata describing the content (data) available from the Content Provider (back-end layer). In this

way, a common understanding of the data, that is, semantic interoperability and openness is achieved. The data manipulated by the system/architecture is described using metadata that comprises of all needed information to unambiguously describe each piece of data and collections of data. This provides semantic interoperability and a human-friendly description of data. This component is directly related to the "New" User Profile component, providing together the most optimized personalized Web-based multimedia content result. It is consisted of three elements:

- **Perceptual Provider Characteristics:** It identifies the provider characteristics assigned to the Web-based multimedia content or multimedia based service. They are involving all these perceptual elements that the provider has been based upon for the design of the content (i.e., actual content/data of the service, layout preferences, content presentation, etc.)
- **Semantic Content Properties:** This element performs the identification and metadata description of Web-based multimedia content or multi-media-based service based on predetermined ontologies. It is implemented in a transparent manner, removing data duplication and the problem of data consistency.
- **Streaming Media Properties:** It contains data transition mechanisms and the databases. These databases contain the Web-based multimedia content or multimedia-based services as supplied by the provider (without at this point being further manipulated or altered).

Back-End Layer (Content Provider)

This is the last layer of the architecture and is directly connected to the middle layer. It contains transition mechanisms and the databases of Web-based multimedia content or multimedia-based services as supplied by the provider without been through any further manipulation or alteration.

The proposed three-layer architecture for adaptation and personalization of Web-based multimedia content will allow users to receive the Web-based multimedia content or multimedia-based service which they access in an adapted style according to their preferences, increasing in that way efficiency and effectiveness of use.

Implementation Considerations

So far, the functionality and interrelation of three-layer achitecture components that provide adapted and personalized Web-based content have been extensively investigated This section will focus on the concepts and parameters that take part in the construction of a comprehensive user profile, and how these could be used in order to collect all the relevant information. As it has already been mentioned, a lot of research has been done for the implementation of the "traditional" user profiling. Many adaptation and personalization techniques have been developed, and common semantic libraries have been set up that give basically specific and ad-hoc solutions.. However, to our knowledge, implementations that incorporate visual attention, cognitive, and emotional processing parameters to the user profile have not been reported as yet, and such parameters would definitely lead to a comprehensive accumulation of user perceptual preference characteristics and hence, provide users with more sustainable personalized content. Therefore, main emphasis in the following section is given to the construction of the "new" comprehensive user profiling, incorporating these user perceptual preference characteristics mentioned above.

Further examining the middle layer of the proposed architecture and the Perceptual User Requirements element of the "New" User Profiling component, we can see that the User Perceptual Preference Characteristics could be described as a continuous mental processing starting with the perception of an object in the users' attentional visual field (stimulus) and going through a number of cognitive, learning, and emotional processes giving the actual response to that stimulus. This is depicted in Figure 5.

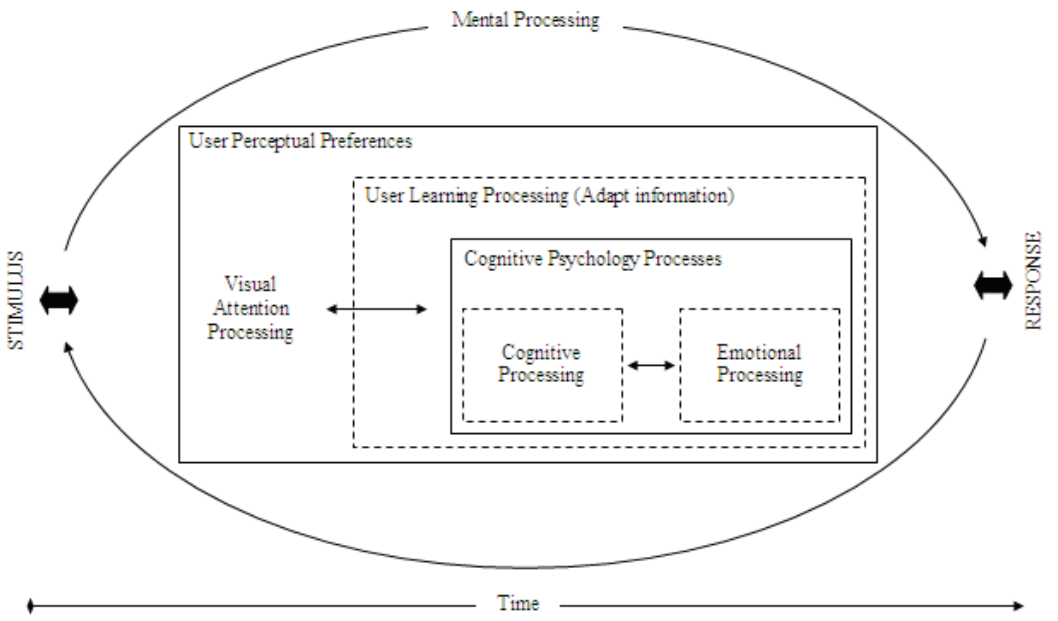
These processes formulate a three-dimensional approach to the problem, as depicted in Figure 6. The three dimensions created are the Learning Styles, the Visual and Cognitive Processing, and the Emotional Processing dimensions.

The *User Learning Processing* dimension is a selection of the most appropriate and technologically feasible learning styles, such as Witkin's Field-Dependent and Field-Independent and Kolb's Learning Styles, being in a position to identify how users transform information into knowledge (constructing new cognitive frames) and if they could be characterized as a converger, diverger, assimilator, accommodator, wholist, analyst, verbalizer, or imager.

The *Visual and Cognitive Processing* dimension is being distinguished from:

- **Visual Attention Processing:** It is composed from the pre-attentive and the limited-capacity stage; the pre-attentive stage of vision subconsciously defines objects from visual primitives, such as lines, curvature, orientation, color, and motion, and allows definition of objects in the visual field. When items pass from the pre-attentive stage to the limited-capacity stage, these items are considered as selected. Interpretation of eye movement data is based on the empirically-validated assumption that when a person is performing a cognitive task, while watching a display, the location of his/her gaze corresponds to the symbol currently being processed in working memory and, moreover, that the eye naturally focuses on areas that are most likely to be informative.

Figure 5. User perceptual preference characteristics

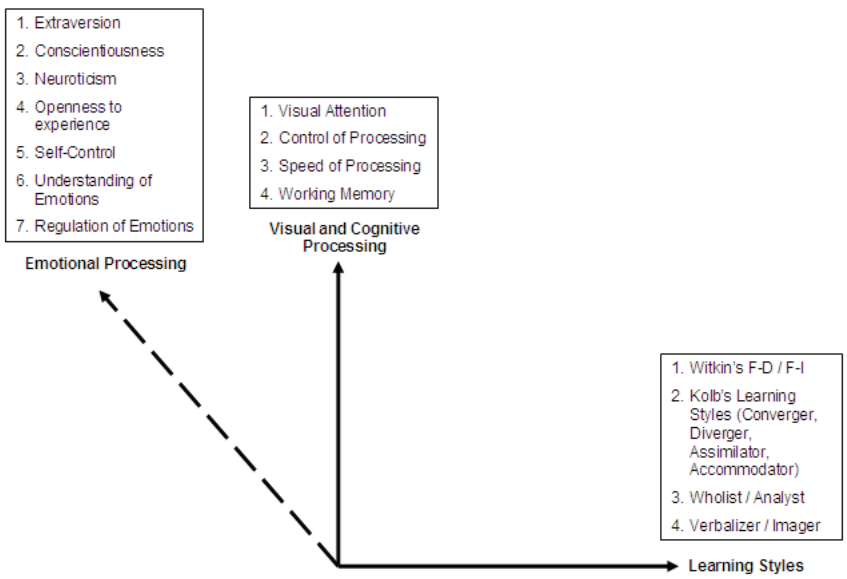


- **Control of Processing:** It refers to the processes that identify and register goal-relevant information and block out dominant or appealing but actually irrelevant information.
- **Speed of Processing:** It refers to the maximum speed at which a given mental act may be efficiently executed (cognitive processing efficiency).
- **Working Memory:** It refers to the processes that enable a person to hold information in an active state while integrating it with other information until the current problem is solved.

The *Emotional Processing* dimension is composed of these parameters that could determine a user's emotional state during the whole response process. This is vital so as to determine the level of adaptation (user needs per time interval) during the interaction process. These parameters include:

- **Extroversion:** Extraverts are sociable, active, self-confident, and uninhibited; while introverts, are withdrawn, shy, and inhibited.
- **Conscientiousness:** Conscientious individuals are organized, ambitious, determined, reliable, and responsible; while individuals low in conscientiousness are distractible, lazy, careless, and impulsive.
- **Neuroticism:** Individuals high in neuroticism are confident, clear-thinking, alert, and content.
- **Open to experience:** Individuals who are open to experience are curious and with wide interests, inventive, original, and artistic; individuals who are not open to experience are conservative, cautious, and mild.
- **Understanding of emotions:** It is the cognitive processing of the emotions; it is the ability of understanding and analysis of the complex emotions and the chain reactions of the emotions, that is, how one emotion generates another.

Figure 6. Three-dimensional approach



- **Regulation of emotions:** It is the control and regulation of personal and other people's emotions for the emotional and intellectual development; it is the human's ability to realize what is hidden behind an emotion, like fear, anxiety, anger, or sadness, and to find each time the most suitable ways to confront them.
- **Self control:** It includes processes referring to the control of attention, the provision of intellectual resources, and the selection of the specialized procedures and skills liable for the evaluation of a problem's results or a decision's uptake; it is a superior control system that coordinates the functioning of other, more specialized control systems.

These parameters must be filtered even more so that the final optimized model is achieved. Once this is established, a series of tests (some in the form of questionnaires and others with real-time interaction metrics) will be constructed which will attempt to reveal users' perceptual preference characteristics. These features, along with the *"Traditional" User Characteristics*, could complete the "New" User Profile, and therefore adaptation and personalization schemes could be adjusted to deliver even more personalized Web-based content accordingly. The next step is to identify what is the correlation between the various users and/or user groups (i.e., to investigate similarities and differences between them) and if it would be feasible to refer to the term "users' segmentation" (i.e., users sharing similar "new" user profiling characteristics). In case the latter is true, personalization mechanisms will be based upon these parameters and considering users' device/channel characteristics, and the semantic content will provide them with the corresponding adapted result. Eventually, this methodology will be implemented with personalization algorithms and paradigms so to automatically gather all the related information and construct the "new" user profiling, giving the users the adapted and personalized result without their actual intervention.

SUMMARY AND FUTURE TRENDS

When referring to adapted multimedia-based services or Web-based multimedia content provision, it is implied that the content adaptation and personalization is based not only on the "traditional" user characteristics, but on a concrete and comprehensive user profiling that covers all the dimensions and parameters of the users preferences. However, knowing the user traditional characteristics and channel/device capabilities, providers can design and offer an apt personalized result. Most of the times, though the providers tend to design multimedia applications based on their own preferences and what they think should be offered. However, the concept of adaptation and personalization is much more complicated than that. This is the reason why until today there is not any sustainable related definition of personalization. A profile can be considered complete when it incorporates the users' perceptual preference characteristics that mostly deal with intrinsic parameters and are very difficult to be technologically measured. Visual attention (that can be thought of as the gateway to conscious perception and memory) and cognitive psychology processes (cognitive and emotional processing parameters) should be in combination investigated and analyzed in a further attempt to complete the desktop and mobile users' preferences.

This chapter made an extensive reference to the mobility emergence and the extensive use of the new channels that tend to satisfy the new user requirements (desktop and mobile) for "*anytime, anyhow, and anywhere*" multimedia-based services and Web-based multimedia content provision in general. The problem of personalization as well as challenges created has been investigated supporting the view of why the provision of adapted content, based on a comprehensive user profile, is considered critical nowadays. Moreover, an Adaptation (Adaptive Hypermedia) and Personalization (Web Personalization) catego-

ries and paradigms review has been presented identifying common grounds and objectives of these two areas. Eventually, a three-layer architecture for the adaptation and personalization of Web-based multimedia content was reviewed, making use of the aforementioned adaptation and personalization concepts and technologies, the new user profiling (that incorporates the user perceptual preference characteristics), as well as the semantic multimedia content..

The basic objective of this chapter was to introduce a combination of concepts coming from different research areas, all of which focus upon the user. It has been attempted to approach the theoretical considerations and technological parameters that can provide the most comprehensive user profiling, supporting the provision of the most apt and optimized adapted and personalized multimedia result.

Chapter 8.4
New Internet Protocols for Multimedia Transmission

Michael Welzl
University of Innsbruck, Austria

ABSTRACT

This chapter will introduce three new IETF transport layer protocols in support of multimedia data transmission and discuss their usage. First, the stream control transmission protocol (SCTP) will be described; this protocol was originally designed for telephony signaling across the Internet, but it is in fact broadly applicable. Second, UDP-Lite (an even simpler UDP) will be explained; this is an example of a small protocol change that opened a large can of worms. The chapter concludes with an overview of the datagram congestion control protocol (DCCP), a newly devised IETF protocol for the transmission of unreliable (typically real-time multimedia) data streams.

INTRODUCTION

For decades, two transport layer protocols of the TCP/IP suite were almost exclusively used: TCP and UDP. The services that these protocols provide are entirely different, and easy to grasp: while the latter simply makes the "best effort" service of the Internet accessible to applications, TCP reliably transfers a stream of bytes across the network. UDP only has port numbers that make it possible to distinguish between several communicating entities which share the same IP address and a checksum that ensures data integrity, but TCP encompasses a large number of additional functions:

- **Stream-based in-order delivery:** Packets are ordered according to sequence numbers, and only consecutive bytes are delivered
- **Reliability:** Missing packets are detected and retransmitted
- **Flow control:** The receiver is protected against overload with a sliding window scheme
- **Congestion control:** The network is protected against overload by appropriately limiting the window of the sender
- **Connection handling:** Since TCP is a connection oriented protocol, it must have the ability to explicitly set up and tear down connections

- **Full-duplex communication:** An acknowledgment (ACK) can also carry user data; this is usually referred to as "piggybacking"

The importance of these mechanisms varies. A protocol could, for instance, easily do without the full-duplex communication capability; on the other hand, some form of end-to-end congestion control has been identified as an indispensable element of any protocol that is to be used on the Internet (Floyd & Fall, 1999). This does however not mean that there is only one way to carry out congestion control: TCP uses an "additive increase, multiplicative decrease" strategy which essentially probes for the available bandwidth by linearly increasing the rate until a limit is hit (causing a packet to be dropped or a congestion signaling bit to be set), whereupon the rate is reduced by half. There are proposals for congestion control that is fair towards TCP ("TCP-friendly") yet more suitable for multimedia applications because the rate fluctuations are less severe. One notable example is "TCP-friendly rate control (TFRC)" (Floyd, Handley, Padhye, & Widmer, 2000).

TCP does not provide the flexibility that today's applications need: it is neither possible to disable any of its aforementioned functions (in particular reliability, which adds delay but is typically not needed by real-time multimedia applications), nor can a user change the way they work (e.g., influence how congestion control is carried out). UDP, on the other hand, allows for more flexibility, but its feature set is so small that any additional protocol function must be implemented directly within the application that uses it. Sometimes, this is unacceptable — realizing TCP-friendly congestion control, for instance, is difficult, and may not be worth the effort from the perspective of a single application designer. Indeed, even the popular streaming media applications "RealPlayer" and "Windows Media Player" do not appear to properly adapt their rate in response to congestion (Hessler & Welzl, 2005).

In this chapter, we will take a look at three novel IETF protocols that change this situation somewhat: the "stream control transmission protocol (SCTP)," "UDP-Lite," and the "datagram congestion control protocol (DCCP)." While SCTP could also be regarded as some sort of a "TCP++," these three protocols share one notable property: they can emulate the behavior of TCP (or UDP, in the case of UDP-Lite), but with *less* features. The ability to effectively *disable* TCP features is therefore a feature in itself; this gives new meaning to the saying "*less is more*." Historically, SCTP is by far the oldest of these protocols; its main specification (Stewart et al., 2000) was published in 2000, and it is now going through the difficult post-standardization phase of achieving large-scale Internet deployment. Notably, the IETF recommends this protocol for authentication, authorization, and accounting (AAA) in any future IP service networks, and SCTP has been required by the 3rd Generation Partnership Project (3GPP) (Stewart & Xie, 2002, p. 17). UDP-Lite was recently published as a "Proposed Standard" — the same status as SCTP — by the IETF (Larzon, Degermark, Pink, Jonsson, & Fairhurst, 2004), and DCCP has not even reached this status yet; at the time of writing, its specification (Kohler, Handley, & Floyd, 2005) was still an Internet-draft, which is a preliminary type of IETF document. The protocol can be expected to become a Proposed Standard RFC in the near future, and its impact could then become quite significant.

THE STREAM CONTROL TRANSMISSION PROTOCOL (SCTP)

SCTP is the result of an effort to develop an efficient Internet transport protocol for telephony signaling. As such, its features are not directly related to the transmission of multimedia data; it was however understood that it is a protocol of broad use, and SCTP can certainly be advanta-

geous for mobile multimedia if the data are suitable and the protocol is used in an intelligent manner. This is because delay is always an important issue for real-time multimedia applications, and reduced delay is exactly what SCTP can give you. In what follows, we will take a closer look at its main features.

Reliable Out-Of-Order but Potentially Faster Data Delivery

TCP suffers from a problem that is called "head-of-line blocking delay": when packets 0, 2, 3, 4, and 5 reach a TCP receiver, the data contained in packets 2 to 5 will not be delivered to the application until packet 1 arrives. This effect is caused by the requirement to deliver data in order. By allowing applications to relax this constraint (this is reasonable for telephony signaling), SCTP can deliver data faster while providing the reliability that UDP lacks.

Preservation of Message Boundaries

Faster delivery of out-of-order packets is only possible if the data blocks can be clearly identified by the protocol. In other words, embedding such a function in a TCP receiver would not be possible because of its byte stream-oriented nature. Moreover, giving the application the power to control the elementary data units that are transferred ("application layer framing (ALF)") can yield more efficient programs (Clark & Tennenhouse, 1990). This is shown in Figure 1. Here, four application chunks are transmitted in four packets. Without ALF, it is possible that just a couple of bytes from chunk 2 end up in packet 1; if packet 2 (which contains the rest of chunk 2) is lost, however, these bytes are of no use at the receiver until the retransmitted packet 2 arrives. Similarly, the loss of packet 2 can affect chunk 3, rendering the correctly received packet 3 useless until the retransmitted packet 2 arrives.

Efficiently choosing the size of packets as a function of the application chunk size does of course not mean that packets have to be exactly as large as chunks — the same advantage can be gained if the packet size is an integral multiple of the chunk size or vice versa.

Support for Multiple Separate Data Streams

Sometimes, an application may have to transfer more than one logical data stream. Mapping multiple data streams onto a single TCP connection requires some effort from an application and can be inefficient. Figure 2 shows an example scenario where packets are reordered inside the network (this is indicated via the bold numbers underneath the TCP sender and receiver buffers, which represent TCP sequence numbers). Clearly, even when the streams themselves call for in-order data delivery, this is not necessarily the case for segments that belong to different streams, and head-of-line blocking delay can occur — in the figure, chunk 2 from application stream 1 can only be delivered when chunk 1 from the otherwise unrelated application stream 2 arrives. This problem is eliminated by the multiple stream support feature of SCTP.

Another common solution to this problem is to simply use multiple TCP connections for multiple application streams, but this also means

Figure 1. An inefficient choice of packet sizes

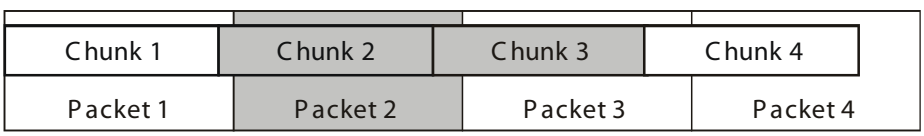

Figure 2. Transmitting two data streams over one TCP connection

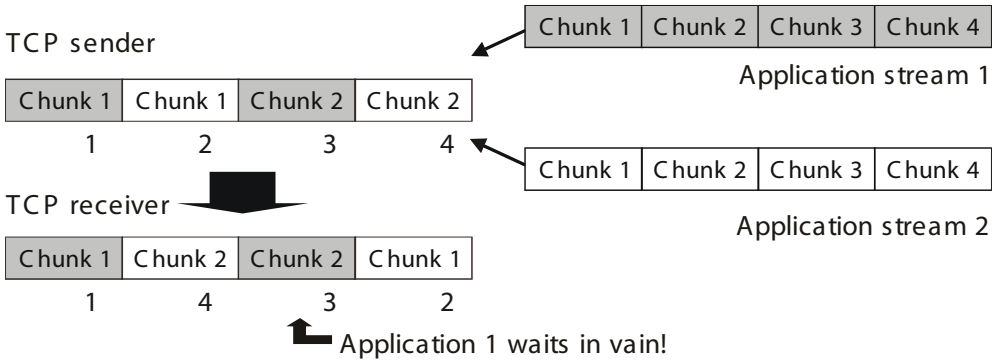

that connection setup and teardown are carried out several times (thereby adding network traffic and increasing delay), and that congestion control is independently executed for each connection, rendering the total behavior of the source more aggressive than it should be (Balakrishnan, Rahul, & Seshan, 1999).

Multihoming

While TCP connections are uniquely identified via two IP addresses and two port numbers, SCTP connections are identified via two sets of IP addresses and two port numbers, and they are actually called "associations" instead of "connections." Multihoming at the transport layer is a powerful concept; it can enable an application to switch from one IP address to another when the communication fails without even noticing it. From the perspective of an application, the transport layer simply becomes more robust when multiple IP addresses are used for an association endpoint. The possible failure is not limited to the machine at the other end—SCTP can also switch when the communication flow is interrupted because of a problem inside the network. This can be used to shorten the time it takes for the network to "repair" an error (e.g., bypassing a failed link—since routing updates are typically sent every 30 seconds, the convergence time of Internet routing protocols can be quite long); SCTP can switch to an alternate address in the meantime and switch back when the problem has been solved. Multihoming may be particularly useful for mobile applications of any kind, where significant handover delays are known to be a common problem.

Partial Reliability

This feature, which was recently added to SCTP in a separate document (Stewart, Ramalho, Xie, Tuexen, & Conrad, 2004), makes it possible for an application to specify how persistent the protocol should be in attempting to deliver a message, including totally unreliable data transfer. This allows for multiplexing of unreliable and reliable data streams across the same connection; the ability to unreliably transfer data with congestion control functionality in place makes the service provided by this usage mode of SCTP quite similar to DCCP with TCP-like behavior (we will get to that later in this chapter), but with the additional benefit of features like multihoming.

UDP-LITE

If we regard SCTP as "TCP++," then UDP-Lite is "UDP++"—or actually "UDP--"—because its only feature is the possibility to restrain or even disable the original UDP checksum (Larzon et al.,

2004). The reason to do so is easily explained: there are video and audio codecs that can deal with bit errors (which can, for example, be caused by link noise in a wireless environment). However, even if only a single bit is wrong, the UDP checksum will fail, causing the receiver to drop the whole packet from the stack. The codec then ends up with a large number of bytes missing, as potentially useful data that actually made it to the receiver were discarded by the operating system.

The UDP-Lite header is very similar to the UDP header—just the "Length" field, which is redundant because the length of a datagram is contained in the IP header, was replaced with a field called "Checksum Coverage." It represents the number of bytes, counting from the beginning of the UDP-Lite header, that are covered by the checksum. Such partial coverage can be useful for certain codecs—the "adaptive multi-rate" and "adaptive multi-rate wideband" audio codecs, for example (Sjoberg, Westerlund, Lakaniemi, & Xie, 2002). In any case, it is mandatory to have the header checked because, without knowing that the header is correct, even the port numbers can be wrong and the whole communication flow becomes meaningless (it is actually possible to disable the checksum altogether in standard UDP, but this feature is rather useless).

Despite its simplicity and its seemingly obvious advantages, UDP-Lite caused a lot of discussions in the IETF. The main problem is the fact that UDP-Lite does not yield any benefits whatsoever unless a link layer technology actually hands over corrupt data. Since it is the first IETF development to have that requirement, link layer technologies were so far optimized for protocols that require data integrity. Typically, there is a strong checksum, and often, corrupt frames are retransmitted with a certain persistence and eventually dropped and not forwarded by the link layer (Fairhurst & Wood, 2002); this is, for example, the case with standard 802.11 wireless LAN systems.[2] UDP-Lite can be seen as being at odds with the notion "IP over everything," as it enables application programmers to write an application that works well in one environment (where there is a small loss ratio) and does not work at all in another. These issues are actually quite intricate; more details can be found in Welzl (2005). In any case, from the perspective of a mobile multimedia application programmer, UDP-Lite is probably an attractive protocol, and after a couple of years of discussion, it has been published as a "Proposed Standard" RFC by the IETF. Since it was designed to be downward compatible with UDP, there is not much harm in using it even though the benefits can only be attained if an underlying link layer hands over corrupt data.

THE DATAGRAM CONGESTION CONTROL PROTOCOL (DCCP)

Multimedia applications are supposed to adapt their rate to the allowed transmission rate of the network in order to prevent Internet congestion collapse; ideally, this should be done in a way that is fair towards TCP ("TCP-friendly"). This is easier said than done: simply using TCP is usually not an option, as most real-time multimedia applications put timely delivery before reliability (i.e., users normally accept some noise in a telephone conversation, but having the sound excessively delayed is intolerable). Thus, such applications use UDP instead of TCP—but UDP provides no congestion control, leaving the task up to its user.

Adapting the rate is generally a difficult issue at the application level: data can be layered, compression factors can be tuned, encodings can be changed, but the outcome is not always precisely predictable. The additional requirement of being fair towards TCP and embedding a complete congestion control mechanism within the application may just be too much for most developers. Moreover, there is an incentive problem here—while TCP-friendliness is definitely desirable from the network point of view, it is questionable whether

implementing this functionality is worth the effort for a single multimedia application developer. Finally, a user space congestion control implementation is just not ideal because precise timing may be necessary.

The IETF seeks to counter these problems with the datagram congestion control protocol (DCCP), which embodies congestion control functions for applications that do not need reliability. This protocol should be used as a replacement for UDP by networked multimedia applications and could be regarded as a framework for TCP-friendly mechanisms; due to a wealth of additional functions, DCCP is indeed an attractive alternative. According to its main specification (Kohler et al., 2005), one way of looking at the protocol is as TCP minus byte stream semantics and reliability, or as UDP plus congestion control, handshakes, and acknowledgments—but in fact, DCCP, includes much more than these three functions. In what follows, we will take a closer look at the most important elements of the protocol.

Connection Handling

Despite being unreliable, DCCP is connection oriented. The main reason for embedding this function in the protocol is to facilitate traversal of middle boxes such as firewalls which can selectively admit or reject communication flows when packets are associated with connections.

Reliable ACKs

Congestion control requires feedback. As in TCP, this takes the form of acknowledgment packets (ACKs) in DCCP—but with different semantics. In TCP, "ACK 2000" means "I received everything up to byte 1999, and I would like to have byte number 2000". Since DCCP never retransmits a packet, such cumulative ACKs would not make much sense here; thus, DCCP ACKs only acknowledge the reception of individual packets. This means that a sender has to maintain state regarding all the packets that were ACKed, and that it is hard for a sender to decide when to remove the state (at a TCP sender, the reception of a cumulative ACK can be used as an indication to remove any state regarding previous packets). It was therefore decided to make ACKs reliable in DCCP, in other words, retransmit them until the ACKs themselves are successfully ACKed. This has the additional advantage that congestion control can be carried out along the backward path—something that is hard to achieve with TCP, where data packets are reliably transferred, but ACKs are not. This fact makes DCCP superior to TCP in highly asymmetric environments such as satellite access links, where incoming data are streamed across a satellite and ACKs are often sent across a low-bandwidth modem link.

Feature Negotiation

In the DCCP specification, the word "feature" refers to a variable which is used to identify whether a DCCP endpoint uses a certain function. The "congestion control ID (CCID)" is an example of such a feature—endpoints must be able to negotiate which congestion control mechanism is to be used. The specification describes exactly how this is done; this includes the possibility to specify a "preference list," which is like saying "I would like CCID 2, but otherwise, please use CCID 1. If you cannot even give me CCID 1, let us use CCID 3." This procedure is another example of a reliable process that is embedded in this otherwise unreliable protocol. Features are specific to one endpoint, which means that a full-duplex DCCP communication flow can use one congestion control mechanism in one direction and another one in the other.

Checksums

As with UDP-Lite, the DCCP checksum can be restricted or even completely disabled. Additionally, the "data checksum" option can be used to

distinguish between corruption-based loss and other loss events even when it is unacceptable to deliver erroneous data to applications. With this mechanism, a DCCP congestion control mechanism can therefore bypass the well-known TCP problem of misinterpreting any kind of packet loss as a sign of congestion (Balan et al., 2001).

Full Duplex Communication

Applications such as VoIP or video conferencing tools may require a bidirectional data stream—here, the full duplex communication capability of DCCP can make things more efficient by piggybacking ACKs onto data packets. Additionally, having only one logical connection for two unidirectional flows facilitates middle box traversal (i.e., firewalls require less state—and making the job easy for firewall developers fosters deployment of the protocol).

Explicit Congestion Notification (ECN) Support

With ECN, routers are given the option to set a bit in packets that they would normally drop (Ramakrishnan et al., 2001); the underlying idea is that a receiver should inform a sender when the "congestion experienced (CE)" bit in the IP header was set by a router, and a sender should react as if the packet had been dropped. With UDP, where the application programmer is responsible of implementing proper congestion control, ECN support could lead to unfairness—after all, who could prevent an application programmer from simply ignoring the bit? Thus, the fact that DCCP makes use of ECN could be seen as a function that makes it somewhat superior over UDP.

Security

DCCP was designed to be at least as secure as a state of the art TCP implementation; modern TCP functions like ECN Nonces (a mechanism that prevents a receiver from lying about the congestion state) (Spring, Wetherall, Ely, 2003) and "appropriate byte counting (ABC)" (Allman, 2003) as well as "cookies" that can reduce the chance for a TCP-SYN-like DoS attack to succeed are therefore part of the protocol.[3] In TCP, sequence numbers automatically yield some protection against hijacking attacks; due to its unreliable nature, this had to be taken care of by means of a special sequence number synchronization procedure in DCCP.

Mobility

Whether to support mobility or not was discussed at length in the DCCP working group; eventually, neither mobility nor multihoming were included in the main document, and the specification was postponed. A rudimentary mechanism that slightly diverges from the original DCCP design rationale of not using cryptography is currently in the works. It is disabled by default, and an endpoint that wants to use this mechanism must negotiate enabling the corresponding feature. The scheme is simpler than mobility support in SCTP and resembles Mobile IP as specified in RFC 3344 (Perkins, 2002); at this point in time, it is unclear if (or when) it will be published as an RFC.

CONCLUDING REMARKS

The sudden appearance of new transport protocols for the Internet may help to make things more efficient, but it certainly will not make them easier to handle. How is an application programmer supposed to know whether, say, SCTP with parameters chosen for unreliable transmission or DCCP with TCP-like behaviour is more suitable for a certain situation? Also, these new transport protocols may face severe deployment problems—there must be a clear incentive for an application programmer to use a new protocol, which always has the potential risk of not

penetrating an outdated firewall. Requiring to update all DCCP-based applications whenever a new CCID becomes defined also does not seem to be very attractive. Many more questions appear on the horizon—for instance, how do RTP and DCCP go together?[4] Finally, experiences with these protocols in mobile environments is quite limited.

While development of these protocols has progressed nicely and already reached a certain level of maturity, their use is still in its infancy. It may take a while until the radical change from TCP and UDP to a total of five transport protocols is welcomed by the majority of application developers; in any case, at this point in time, putting some research efforts into studying their usage in different scenarios seems to be a good idea.

KEY TERMS

Application Layer Framing (ALF): Putting an application in control of block sizes that are transferred across the network.

DCCP: Datagram congestion control protocol.

Head-of-Line Blocking Delay: Delay that is caused by the requirement to deliver data chunks in order.

Multihoming: Associating a single logical connection endpoint with multiple IP addresses.

SCTP: Stream control transmission protocol

ENDNOTES

1. Internet Engineering Task Force–the technical standardization body of the Internet.
2. WiMAX (802.16) is a counter-example: here, it is possible to disable the checksum, albeit for reasons of compatibility with ATM.
3. Cookies can also be found in the SCTP association setup procedure (Stewart & Xie, 2002).
4. The answer to this question is: while DCCP functions could theoretically be implemented on top of RTP, it was decided that having RTP run over DCCP would be the right way to proceed.

Chapter 8.5
Future Directions of Multimedia Technologies in E-Learning

ABSTRACT

In the last chapter, we discuss how advanced multimedia technologies are used in distance learning systems, including multimedia authoring and presentation, Web-based learning, virtual environments, interactive video, and systems on mobile devices. On the other hand, we believe pedagogic theory should be incorporated into the design of distance learning systems to add learning efficiency. Thus, we point out some suggestions to the designers of future distance learning systems.

INTRODUCTION

Distance learning, based on styles of communication, can be categorized into synchronized and asynchronized modes. The advantages of distance learning include flexibility of time and space, timely delivery of precisely presented materials, large amount of participants and business opportunity, and automatic/individualized lecturing to some degrees. Both synchronized and asynchronized distance learning systems rely on multimedia and communication technologies. Due to its commercial value, distance learning is becoming a killer application of multimedia and communication research. We discuss current distance learning systems based on the types of

multimedia technologies used and point out a few new research directions in the last section.

MULTIMEDIA PRESENTATIONS AND INTERACTIONS

Authoring and playback of multimedia presentations are among the earliest applications of multimedia technologies. Before real-time communication and video-on-demand technologies, multimedia presentations were delivered to kids and distance learning students on CD ROMs. The advantage of multimedia presentation over traditional video tapes is due to interactivity. Multimedia presentations allow one to select "hot spots" in individualized topology. Techniques to realize this type of CD ROM presentations allow a rich set of media coding and playback mechanisms, such as images, sounds, and animations (including video and motion graphics). Successful examples include MS PowerPoint, Authorware Professional, Flash, and others.

With the development of communication technologies, multimedia computing focuses on efficient coding mechanism to reduce the amount of bits in transmission. Synchronization among media became important. Inner stream synchronization is implemented in a single multimedia record, such as the interleaving coding mechanism used in a video file, which includes sound track and motion picture track. Another example of inner stream synchronization and coding is to merge graphics animation with video stream (Hsu, Liao, Liu, & Shih, 2004). On the other hand, inter stream synchronization is more complicated since both the client (i.e., user) side and the server (i.e., management system) side need to work together. Inter stream synchronization allows packages (e.g., sound and image) to be delivered on different paths on a network topology. On the client side, packages are re-assembled and ensured to be synchronized. Another example of a recent practical usage of inter stream synchronization is in several commercial systems allowing video recording to be synchronized with MS PowerPoint presentation or Flash. Some systems (Shih, Wang, Liao, & Chuang, 2004) use an underlying technology known as the advanced streaming format (ASF) of Microsoft. ASF allows users or programs to embed event markers. In a playback system on the client side, users can interrupt a vide presentation, or jump to another presentation section. The video presentation can also use markers to trigger another presentation object such as to bring up a PowerPoint slide (converted to an image) or another multimedia reference. In order to deliver a synchronized presentation, an ASF server needs to be installed on the server machine.

ASF provides a preliminary technology for video-on-demand (or lecture-on-demand). In order to support multiple clients, it is necessary to consider bandwidth allocation and storage placement of video records. Video-on-demand systems (Hua, Tantaoui, & Tavanapong, 2004; Mundur, Simon, & Sood, 2004 allow a video stream to be duplicated and broadcast in different topology on multiple channels, to support multiple real-time requests in different time slots. In addition, adaptive coding and transmission mechanism can be applied to video-on-demand systems to enhance overall system performance.

Video-on-demand allows user interactions to select video programs, perform VCR-like functions, and choose language options. Interactive TV (Liao, Chang, Hsu, & Shih, 2005) further extends interactivities to another dimension. For instance, the users can select the outcome of a drama, refer to specification of a commercial product, or answer questions pre-defined by an instructor. The authoring and playback system developed in Liao, Chang, Hsu, and Shih (2005) takes a further step to integrate video browser (for interactive TV) and Web browser. Thus, distance learning can be implemented on set-top box.

WEB-BASED DISTANCE LEARNING AND SCORM

Most multimedia presentations can be delivered online over Internet. And, Web browser is a common interface. HTML, XML, and SMIL are the representation languages of learning materials. Typically, HTML is used in the layout while other programming languages (such as ASP) can be used with HTML to retrieve dynamic objects. As an extension to HTML, XML allows user defined tags. The advantage of XML allows customized presentations for different Web applications, such as music and chemistry, which requires different presentation vocabularies. In addition, SMIL incorporates controls for media synchronization in a relatively high level, as compared to inner stream coding technologies. HTML-like presentations can be delivered by Web servers, such as Apache and MS IIS.

Although Web browsers are available on different operating systems and HTML-like presentations can be reused, search and reuse of course materials, as well as their efficient delivery, are key issues to the success of distance learning. In order to achieve reusability and interoperability, a standard is needed. The advanced distributed learning (ADL) initiative proposed the sharable content object reference model (SCORM) (The Sharable Content Object Reference Model, 2004) standard since 2000. Main contributors to SCORM include the IMS Global Learning Consortium, Inc., the Aviation Industry CBT (computer-based training) Committee (AICC), the Alliance of Remote Instructional Authoring & Distribution Networks for Europe (ARIADNE), and the Institute of Electrical and Electronics Engineers (IEEE) Learning Technology Standards Committee (LTSC). The SCORM 2004 (also known as SCORM 1.3) specification consists of three major parts

- **The content aggregation model (CAM):** Learning objects are divided into three categories (i.e., assets, sharable content objects (SCOs) and content organizations). The contents of the learning objects are described by metadata. In addition, CAM includes a definition of how reusable learning objects are packed and delivered.
- **The run-time environment:** In order to deliver learning objects to different platforms, a standard method of communication between the learning management system (LMS) and the learning objects is defined.
- **The sequencing and navigation:** Interactions between users (i.e., students) and the LMS are controlled and tracked by the sequencing and navigation definitions. This also serves as a standard for defining learner profiles, as well as a possible definition for intelligent tutoring.

The SCORM specification clearly defines representation and communication needs of distance learning. To realize and promote the standard, a few SCORM-compliant systems were implemented (Chang, Chang, Keh, Shih, & Hung, 2005; Chang, Hsu, Smith, & Wang, 2005; Shih, Lin, Chang, & Huang; Shih, Liu, & Hsieh, 2003). However, common repository for SCORM learning objects, representation of learner records, and intelligent tutorial mechanisms to facilitate sequencing and navigation are yet to be identified. On the other hand, most existing SCORM-compliant LMSs fail to support the newest specification, except the prototype provided by ADL.

VIRTUAL CLASSROOM AND VIRTUAL LAB

Web-based distance learning supports asynchronized distance learning in general. Usually, distance learning programs rely on Web browsers to deliver contents, collect assignments from students, and allow discussion using chat room or e-mails. These functions can be integrated in a

distance learning software platform such as Blackboard (http://www.blackboard.com/) and WebCT (http://www.Webct.com/). On the other hand, real-time instruction delivery can be broadcast using video channels, or through bi-directional video conferencing tools (Deshpande, & Hwang, 2001; Gemmell, Zitnick, Kang, Toyama, & Seitz, 2000). Real-time video communication requires sophisticated network facilities and protocols to guarantee bandwidth for smooth transmission.

In addition to online delivery of instruction, lab experiments can be realized using remote labs or virtual labs (Auer, Pester, Ursutiu, & Samoila, 2003). Remote lab uses camera and advanced control technologies to allow physical lab instruments to be accessed by students using Internet. Virtual lab may or may not include physical experimental instruments. Emulation models are usually used. In most cases, assessment of experiment outcomes from software emulation is compared with those from physical devices.

Virtual reality (VR) and augmented reality techniques can also be used in distance learning (McBride & McMullen, 1996; Shih, Chang, Hsu, Wang, & Chen, 2004). Most VR systems use VRML, which is an extension of XML for 3-D object representations. The shared-Web VR system (Shih, Chang, Hsu, Wang, & Chen, 2004) implements a virtual campus, which allows students to navigate in a 3-D campus, with different learning scenarios. Behaviors of students can be tracked and analyzed. The incorporation of game technologies points out a new direction of distance learning, especially for the design of courseware for kids. With wireless communication devices, ubiquitous game technologies can be used for mobile learning in the near future.

MOBILE LEARNING

Wireless communication enables mobile learning. With the capability of multimedia technologies on wireless connected notebook computers, PDAs, and even cellular phones, system developers are possible to implement distance learning systems on mobile devices (Meng, Chu, & Zhang, 2004; Shih, Lin, Chang, & Huang, 2004). The challenges of deploying course materials on small devices, such as cellular phones, include the limited display space, slow computation, and limited memory capacity. On a small display device, reflow mechanism can be implemented (Shih, Lin, Chang, & Huang, 2004). The mechanism resizes contents into a single column layout, which can be controlled using a single scroll bar on PDAs or cellular phones. To cope with small storage, prefetching technique on subdivided course contents can be used. Thus, the readers can download only the portion of contents of interesting.

To realize learning management systems on wireless network connected devices, a distributed architecture needs to be designed between the server and the client (e.g., PDA). SOAP is a communication protocol very suitable for the architecture. SOAP packages are messages that can be sent between a client and server, with a standard representation envelope recommended by the W3C (http://www.w3.org/). The advantages of the protocol include platform independency, accessibility, and implementation efficiency. In addition, in order to maintain the status of each individual learner, learner profiles needs to needs to be defined. Yet, SCORM contains only a preliminary description of learner profile definition. The representation of course contents should also consider how to enable small packages to be delivered on a remote request. Cashing mechanism and hand shaking protocol are important issues yet to be developed. In addition, in some occasion for situated learning, location awareness is necessary for situated collaborative learning.

On the other hand, synchronized distance learning on mobile devices requires efficient real-time streaming due to the limited bandwidth of current wireless communication systems (Liu, Chekuri, & Choudary, 2004. Even as 3G mobile communication technologies are avail-

able, smooth video streaming requires a broader channel and a robust error resilience transmission mechanism.

HYBRID INTERACTIVE SYSTEMS AND PEDAGOGICAL ISSUES

Whether learning activities are implemented on mobile devices or PC clients, efficient collaboration is the key issue toward the success of learning. A SCORM-based collaborative learning LMS is developed in Chang, Lin, Shih, and Wang (2005). The system allows learning activities among students to be synchronized based on the Petri net model. The instructor is able to supervise the collaboration behavior among a group of students. Whether or not it is SCORM compliant, a distance learning platform should support collaboration in either synchronized or asynchronized manner. At least, a CSCW-like system should be implemented to support the need of collaboration.

Recently, personalized Web information delivery has become an interesting issue in data mining research. A distance learning server is able to analyze student profiles, depending on individual behaviors. Learner profiles can be stored and analyzed according to traversal sequences and results from tests. This type of distance learning system is based on the self-regulation principles of the social cognitive theory (Bandura, 1986). A system using this approach should allow students to plan on their study schedule based on individual performance (Leung, & Li, 2003), while the underlying intelligent mechanism can guide students to a suitable study schedule, which can be reviewed by an instructor. To facilitate user friendliness, self-regulation can be incorporated with Web-based interfaces and mobile devices. To some degree of the usage of artificial intelligence (Shih & Davis, 1997), an intelligent tutorial system is able to generate individualized lectures (Leung & Li, 2003).

We realize that, it is possible to design an integrated learning environment to support the application of the scaffolding theory (Zimmerman & Schuck, 1989). Scaffolding, proposed by L. S. Vygotsky, was viewed as social constructivism. The theory suggests that students take the leading role in the learning process. Instructors provide necessary materials and support. And, students construct their own understanding and take the major responsibility. Between the real level of development and the potential level of development, there exists a zone of proximal development. This zone can be regarded as an area where scaffolds are needed to promote learning. Scaffolds to be provided include vertical and horizontal levels as a temporary support in the zone of proximal development. The scaffolding theory is essential for cognitive development. It also supports the process of social negotiation to self-regulation. There are three properties of the scaffold

- The scaffold is a temporary support to ensure the success of a learning activity.
- The scaffold is extensible (i.e., can be applied to other knowledge domains) and can be used through interactions between the learner and the learning environment.
- The scaffold should be removed in time after the learner is able to carry out the learning activities independently.

The scaffolding theory indicates three key concepts. Firstly, in the zone of proximal development, the relationship between the scaffolds providers and the receivers are reciprocal. That means that the instructor and students negotiate a mutual beneficial interactive process. Secondly, the responsibility is transferred from the instructor to the student during the learning process. Depending on the learning performance, the instructor gradually gives more control of the learning activities to the student for the ultimate goal of self-regulation. Finally, the interaction facilitates the learners to organize their own

knowledge. Scaffolding also encourages the use of language or discourse to promote reflection and higher-order thinking.

Pedagogical principles are not multimedia technology. However, the developers of distance learning system should be aware of the concept.

SUMMARY

This chapter summarizes multimedia technologies for distance learning systems. While we were looking for the essential needs of professional educators and students, in terms of "the useful multimedia distance learning tools," we have found that lots of tools were developed by computer scientists. Most of these tools lack of underlying educational theory to show their usability. However, software is built for people to use. In spite of its advanced functionality and outstanding performance, any system will be useless if no one uses it. Thus, we believe the specification of a distance learning system should be written by educational professionals, with the help of computer scientists.

From the perspective of multimedia and Internet computing, there are a few challenging research issues to make distance-learning systems more colorful and useful. We highlight a few here

- **Interactive TV:** Video-on-demand technologies should be highly integrated with interactive TV and set-top box devices, which should be extended to incorporate different modals of interaction. A sophisticated bi-directional inter stream synchronization mechanism needs to be developed.
- **Standards:** The most popular standard is SCORM. However, the definition of user profile, federal repository, and adaptive techniques for mobile devices are yet to be investigated.
- **High communication awareness:** Video conferencing tools should be integrated with awareness sensors, to bring the attentions on interested video area to users.
- **Virtual and remote lab:** A standard development specification for creating virtual or remote labs is not yet developed. The standard should allow reusable lab components which can be assembled to facilitate different varieties of lab designs.
- **Adaptive contents for mobile learning:** Different mobile devices should have different functional specifications to guide a central server to transmit device and user dependent media for efficient learning.
- **Intelligent tutoring:** User profile dependent tutoring based on intelligent technology applied on Web technology should be used. Pedagogical considerations can be applied on intelligent tutoring.

Among the developed platforms for distance learning, an assessment mechanism, especially the one based on educational perspective, should also be proposed. It is the hope that the multimedia research community can work with educational professionals and the distance learning industry together, to develop a standard distance-learning framework for the success of our future education.

Chapter 8.6
Toward Effective Use of Multimedia Technologies in Education

Geraldine Torrisi-Steele
Griffith University, Australia

ABSTRACT

While multimedia technologies are being used in educational contexts, the effective use of multimedia in these contexts remains problematic. In an attempt to contribute towards addressing this problem, this chapter presents a set of conceptual guidelines and a practical planning framework that is intended to inform the planning and design of more effective multimedia integration into educational contexts. A mixed-mode approach is advocated in this chapter. Multimedia technologies are viewed as part of a tool-set and tool selection should be appropriate to curriculum content and to the teaching and learning context.

INTRODUCTION

Whether or not multimedia technologies should be used in educational contexts seems to no longer be an issue. Multimedia technology is pervading almost all aspects of existence. The rationale for its use in educational contexts is grounded in social, economic, and pedagogical reasons. However, what does remain problematic is the effective use of multimedia technology in educational contexts. At the crux of addressing this problem is the notion that effective integration of multimedia in the curriculum depends not on the technology itself but rather on educators' knowledge, assumptions, and perceptions regarding the technology and its implementation in the specific learning context (Jackson & Anagnotopoulou, 2000; Bennet, Priest, & Macpherson, 1999). From a pedagogical perspective, it is generally accepted that multimedia technologies have the potential to reshape and add a new dimension to learning (Relan & Gillani, 1997; Lefoe, 1998). In reality, however, this potential has largely failed to be realized. The fundamental belief underlying this chapter is that this potential will only be realized by informed pedagogical decision making and the formulation of teaching strategies designed to

exploit multimedia technologies for maximum effectiveness within a particular learning situation. From this perspective, educator development that focuses on pedagogical change is a pivotal aspect of the effective use of multimedia technologies in educational contexts.

The term "multimedia technologies" is being used in this chapter to mean the entirely digital delivery of content using any integrated combination of audio, video, images (two-dimensional, three-dimensional), and text. In its most primitive form, the term "multimedia" is sometimes defined as content presentation using a combination of media [i.e., sound, images (static, moving, animated, video), and text]. From this perspective, any presentation that involves the use of, for example, face-to-face teaching, video recorder, and a slide show could be considered multimedia.

The distinguishing feature of digital multimedia, as used in this chapter (as opposed to the primitive form defined above), is the capacity to support user interaction. Hence, the term "multimedia technologies," as used in this chapter, will always imply that there is an element of "interactivity" present. The concept of interaction is considered along two dimensions: the capacity of the system to allow an individual to control the pace of presentation and to make choices about which pathways are followed to move through the content, and the ability of the system to accept input from the user and provide appropriate feedback to that input. Multimedia technologies may be delivered on computer via CD-ROM, DVD, or via the Internet, or on other devices such as mobile phones and personal digital assistants capable of supporting interactive and integrated delivery of digital audio, video, image, and text data. Multimedia technologies as referred to in this chapter also encompass new communications technologies such as e-mail, chat, and videoconferencing. Virtual reality technologies are also included.

It will be argued later in this chapter that various multimedia technologies are seen as part of a tool set or possible modes of instruction. Other modes include face-to-face teaching, print materials, and video and audio devices. A "mixed-mode" approach will be advocated in this chapter based on the argument that tool selection should be appropriate to curriculum content and to the teaching and learning context.

The contents of this chapter have been based largely on the author's professional development experiences with tertiary educators implementing online learning. However, the ideas discussed in this chapter are based on principles of good practice that apply to a broad range of teaching and learning contexts, including primary, secondary, tertiary, and other training environments.

Against this background, this chapter aims to provide a set of conceptual guidelines and a practical foundation (in the form of a planning framework) that will be of interest to those involved in planning and designing appropriate professional development targeted at promoting effective multimedia integration, and to individual educators in primary, secondary, tertiary, and other training environments who wish to implement multimedia technologies more effectively into the curriculum.

MULTIMEDIA TECHNOLOGIES IN LEARNING ENVIRONMENTS

When computer-based interactive multimedia emerged in the 1990s, innovative educators began considering what implications this new media might have if it was applied to teaching and learning environments. Within a relatively short time frame, the emerging multimedia and associated communications technologies infiltrated almost every aspect of society. So, what was initially viewed as a technology "option" in educational contexts has for social, economic, and pedagogical reasons become a "necessity." Many educational institutions are investing considerable time, effort, and money into the use of technology.

Socially, computer literacy is an essential skill for full participation in society. The use of multimedia technologies in educational institutions is seen as necessary for keeping education relevant to the 21st century (Selwyn & Gordard, 2003).

Economically, the belief prevails that the large-scale use of new multimedia and associated communication technologies for teaching and learning may offer cheaper delivery than traditional face-to-face and distance education and will also help establish and maintain competitive advantages for institutions by allowing them to tap into overseas markets (Bennet, Priest, & Macpherson, 1999, p. 207).

The pedagogical basis for the use of educational multimedia technologies has perhaps been the greatest driving force for the massive investments made by educational institutions into multimedia technologies. Literature abounds with rhetoric about the potential impact of multimedia technologies on traditional teaching practices. The central theme is that the integration of multimedia technologies will lead to a transformation of pedagogy from traditional instructivist teacher-centered approaches to the more desirable constructivist learner approaches that are seen as embodying essential characteristics of more effective learning environments (Tearle, Dillon, & Davis, 1999; Relan & Gillani, 1997; Willis & Dickson, 1997; LeFoe, 1998; Richards & Nason, 1999). From the learner-centered perspective, the teacher's role changes from the traditional (instructivist approach) role of instructor and supplier of knowledge to a role more closely aligned with support and facilitation of the active construction of knowledge by the learner (Tearle, Dillon, & Davis, 1999). The learner-centered approach implies empowerment of the individual learner and the ability to provide the learner with self-directed, more meaningful, authentic learning experiences that lead to lifelong learning. This implication is at the crux of constructivist-based pedagogical arguments for the integration of multimedia technologies in educational contexts (Selwyn & Gorard, 2003; Gonzales et al., 2002).

However, despite the well-documented and generally accepted potential of multimedia technologies to reshape teaching practices, it has been identified in literature that the promised impact of multimedia technologies on learning and pedagogical practices have largely not eventuated. There are relatively few positive impacts on educational practices for major investments of time, effort, and money by educational institutions (Cuban, 1986; Hammond, 1994; Oliver, 1999; Nichol & Watson, 2003; Conlon & Simpson, 2003; Selwyn & Gorard, 2003).

The reason for this lack of impact is seen to lie not with the attributes of the technology itself, but rather with the ways in which the technology has been implemented in learning contexts. More specifically, it is the educators' knowledge, assumptions, and perceptions regarding the technology and its implementation in the specific learning context that will determine its implementation and, hence, its effectiveness (Jackson & Anagnotopoulou, 2000; Bennet, Priest, & Macpherson, 1999). As is often noted in literature, the potential of multimedia technologies to reshape learning contexts (Relan & Gillani, 1997; Lefoe, 1998) will only be realized by informed pedagogical decision making and the formulation of teaching strategies designed to exploit multimedia technologies within the curriculum context.

Although it may be recognized by educators that multimedia technologies have the potential to offer new and improved learning opportunities, many educators fail to realize this potential. A number of educators using multimedia technologies in their learning environments are largely limiting its use to a tool for data access, communication, and administration (Conlon & Simpson, 2003). This is an "add-on" approach to multimedia technology use rather than a truly integrated curriculum approach. This lack of true integration results in minimal (if any) change in both pedagogical strategies and learning environment (Tearle, Dillon, & Davis, 1999; Strommen, 1999).

Failure to implement effective technology integration is attributed to the fact that educators, even experienced educators, are generally unprepared for the changes demanded by and produced by "technology infusion" (Charp, 2000). While some of the pedagogical "know how" of more traditional learning environments possessed by educators may transfer to new interactive multimedia contexts, educators often lack the skills and technical and pedagogical knowledge to effectively implement those technologies in their learning environments. Rakes and Casey (2002, online) observed the following:

…many [educators], especially more experienced teachers, have been unable to find effective ways to use technology in their classrooms. One possible explanation for this lack of success is that the use of technology in the classroom has been viewed in terms of simple skill acquisition instead of as a change process that affects the behavior of individuals on a very profound level.

If there is a lesson to be learned from the last few decades of "educational technology" development, it is that technologies themselves offer very little to the learning process. Conlon & Simpson (2003, p. 149) warned that if educators are "hastened" into adopting multimedia technologies without any clear educational vision of change, then significant transformation of teaching practice is unlikely. The importance of focus on educator development and resources that will foster continuous pedagogical growth and "re-engineering" becomes self-evident and is well documented in literature (Gonzales et al., 2002; Burns, 2002; Pierson, 2001; Charp, 2000; Collis, 1996; Rakes & Casey, 2002).

Against this context, some of the key issues that need be addressed in educator development will be identified and discussed. Five key guidelines and a planning framework for facilitating more effective multimedia technologies integration will be presented.

TOWARD MORE EFFECTIVE TECHNOLOGY INTEGRATION

The preceding discussion has directed attention to the notion that while multimedia technologies have the potential to reshape practice, the potential is often unrealized due to the fact that educators are often ill-equipped to meet the challenges of change demanded by multimedia technologies and to exploit change made possible by them. This notion is supported by an earlier study (Torrisi & Davis, 2000) conducted by the author into the experiences of tertiary educators developing online multimedia materials.

The data from the study highlight some of the key issues that need to be addressed in educator development efforts. Educators in the study were asked to identify what they believed were key competencies that students should develop as a result of undertaking study in the subject. Each educator was also asked to clarify what they believed to be the role of online materials in their course. Table 1 juxtaposes individual educator's responses for key competencies against the educator's stated intended use of online materials. Upon examination of responses as shown in Table 1, a lack of congruency between what educators identified as key competencies for their students and the stated use of online materials was found. This lack of congruency between stated key competencies and intended use of online materials is indicative of multimedia technology that is not truly integrated with the curriculum goals, content, objectives, and context, rather use is limited to being add-on or supplemental.

Insight into reason for supplemental use of multimedia technologies was revealed in interviews with the tertiary educators, whose comments suggested they perceived the use of multimedia online technologies as an exercise in translating materials into another medium, mostly for access and alternative to face-to-face or printed content delivery. This perception of technology use does not foster pedagogical change. It leads to

Table 1. Comparison of stated key competencies cited by teaching staff as important for students to acquire for their subject area to staff member's stated intended use of the online materials

Key competencies as stated by individual educators for students in their by individual	**Intended use of the online materials as stated educators teaching/subject area**
Educator A • Critical analysis • Ability to research • Standard academic writing skills	• *An adjunct to face-to-face teaching; students could access lectures if they could not come to lectures* • *It's the way things are going*
Educator B • Rhythmic perception • Rhythmic literacy • Programming skills	• *Wanted to have a more efficient way of doing things* • *Students access the materials (notes, exercises) before coming to lectures* • *To decrease degree of coordination because links are made obvious on the Web page* • *Access to materials off campus*
Educator C • Challenge their assumptions • Analyze the thinking, underlying practices • Connect theoretical material with their own life experiences • Think through how values can be incorporated into a real-life situation	• *A Web site that students could move around in rather than work linearly and that would get them thinking; to really engage them* • *Wanted to use class contact time for students to engage with each other on the basis of content they already encountered rather than using time for presenting content alone*
Educator D • Analytical skills • Mathematical skills • The case study approach is commonly used.	• *Resource that would be accessed in tutorials* • *To reduce but not replace lecture hours eventually*
Educator E • Develop problem-solving skills • Understand the material covered rather than just memorize it, and then apply what they have been taught to new situations • Become more creative in the tasks assigned	• *The key advantage to the students was greater accessibility and a more convenient way of delivering of course materials* • *Through supplementary activities such as reading, research, foresee what is going to be taught and contribute more to the class, rather than "being a clean slate" when material is presented*
Educator F • Analysis, synthesis, creativity • Develop an analytical way of thinking and problem analysis	• *Resource would have the same attributes as opening a book* • *Students have access to the content, but it really is only an add on*

counterproductive strategies that replicate more traditional methods with the new medium. The result is no impact or even negative impact on the learning environment. Rather, what is required is conceptualization of multimedia technology use in educational contexts as a process of transformation that acknowledges, and strives for, change in practice. In addressing this problem, it is useful to consider the idea of progressive technology adoption found in the literature.

Sandholtz, Ringstaff, and Dwyer (1997) suggested that supplemental use of multimedia technologies as was observed in this study should be viewed as the first stage of a continuum of change that culminates in a third stage of full integration and transformation of practice. The idea of progressive technology adoption is supported by others. For example, Goddard (2002) recognized five stages of progression: knowledge (awareness of technology existence); persuasion (technology as support for traditional productivity rather than as curriculum related); decision (acceptance or rejection of technology for curriculum use—acceptance leading to supplemental uses); implementation (recognition that technology can help achieve some curriculum goals); and confirmation (use of technology leads to redefinition of the learning environment—true integration leading to change).

It is proposed here that framing the educational use of multimedia technologies in terms of progressive levels of use and integration is valuable in that it forces conceptualization of effective technology integration as a process of "change" inherently leading to practice transformation rather than as simple skill acquisition required for translation of materials into a new medium.

Adopting the view that technology integration is a process leading to transformation and innovation directs attention also to the need to include elements of reflective practice in any educator development guidelines and frameworks. The term "reflective practice" is being used here to encompass the idea that educators consciously make judgments about their performances and success of strategies. The notion of evaluation (both formal and informal) is inherent in the idea of reflective practice. According to Ballantyne, Bain, and Packer (1999), lack of reflection leads to lack of awareness of the "appropriateness of…methods in bringing about high quality student learning" (p. 237), resulting in the perpetuation of traditional or ineffective teaching methods. The need for educators to reflect on their practices cannot be understated. Development of new strategies that appropriately integrate multimedia technologies into the curriculum will only take place, according to Tearle, Dillon, and Davis (1999), when the educator has "re-examined his or her approach to teaching and learning" (p. 10).

In the 2000 study conducted by Torrisi and Davis, another key finding was that among the concerns about the production process by educators, the principal concern was the lack of knowledge about the attributes and possibilities of the media and feelings of inadequacy in terms of how to exploit the potential of the media available. Consistent with other findings on professional development (Ellis, O'Reilly, & Debreceny, 1998), it appears that educators are primarily interested in learning the technical aspects of multimedia technologies only insofar as this knowledge is useful in informing pedagogical decisions and options. The implication of this observation is that teaching development efforts aimed at effective integration of multimedia technologies in educational contexts must teach educators how to use the technology within the context of "matching the needs and abilities of learners to curriculum goals" (Gonzales et al., 2002, p. 1).

The view upheld in this chapter is that using multimedia technologies within the curriculum context implies appropriate use of technologies. This view of appropriate technology use supports a mixed-mode approach to curriculum design. That is, the emphasis is on exploiting the attributes of various multimedia technologies and other strategy options in terms of their appropriateness

to content requirements, context, learner needs, and curriculum goals. Some guidelines and a development framework that encapsulate these views are discussed below.

GUIDELINES AND A DEVELOPMENT FRAMEWORK

In the discussion above, some key issues to be addressed in teacher development resources and approaches have been identified by drawing upon data from an earlier study (Torrisi & Davis, 2000). The author's perspective on addressing those issues was also alluded to. Drawing on issues identified in the preceding sections, this section presents the following:

1. A set of guidelines useful for guiding educator development activities
2. A planning framework that may be used to guide teacher development or by individual teachers in order to facilitate the effective integration of multimedia technologies in learning environments

A brief case study is also described in order to illustrate implementation of the notions presented.

Educator Development Activities: Five Key Guidelines

It has been established in the preceding sections that while multimedia technologies are seen as having the potential to reshape practice, the fact remains that implementation often results in little impact on the teaching space. The attributes of the multimedia technologies are not effectively exploited to maximize and create new learning opportunities. At the crux of this issue is the failure of educators to effectively integrate the multimedia technologies into the learning context. The following guidelines are suggested for guiding educator development toward the effective integration of multimedia technologies into learning environments.

- ***Guideline 1:*** **The goal of implementing multimedia technologies into learning spaces is to exploit the attributes of multimedia technologies in order to support deeper, more meaningful learner-centered learning. Realization of this goal necessarily transforms the teaching and learning space.** The knowledge-delivery view of multimedia technologies must be challenged, as it merely replicates teacher-centered models of knowledge transmission and has little value in reshaping practice. Constructivism is the guiding philosophy.
- ***Guideline 2:*** **Transformation is only achieved through integration of multimedia technologies into the learning space.** Integration implies that technology use is inextricably linked with the total curriculum as opposed to the superficial add-on approach that is the result of a view of translation.
- ***Guideline 3:*** **Integration and subsequent transformation is achieved via an ongoing evolutionary process through which educators' knowledge of multimedia technologies draws more closely toward inextricable linkages with curriculum goals and the educator's knowledge of pedagogy.**
- ***Guideline 4:*** **Equipping educators with knowledge about the potential of the multimedia technologies must occur within the context of the total curriculum needs** rather than in isolation of the academic's curriculum needs.
- ***Guideline 5:*** **Evolutionary process leading to transformation and integration of multimedia technologies is fueled by sustained reflection on practice.** Sustaining reflection on practice from the beginning of

> endeavors in online materials development through to completion stages, after which debriefing and further reflection feed back into a cycle of continuous evolution of thought and practice. Collaborative work and sharing of experiences and ideas with other educators is also of benefit here.

In addition to the above guidelines, two considerations as identified by Torrisi and Davis (2000) are important to recognize as contributing to effective professional development conducive to long-term transformation in practice.

First, it is important that professional development programs are not designed in isolation of the educators operating context. Traditional training workshops removed from the immediate teaching context of the educator fail to be effective. Programs must empathize with and address concerns that arise from educators' earlier attempts at innovation through technology. Ongoing support opportunities, both technical and pedagogical, must be inextricably linked with educators' everyday practice. If appropriate technology use is to be a reality, then professional development must do as Fatemi (1999) stated:

…more than simply show teachers where in a curriculum they can squeeze in some technology.... Instead, it helps them learn how to select digital content based on the needs and learning styles of their students, and infuse it into the curriculum rather than making it an end in itself. (p. 1)

Professional development programs will be most effective, as Bennet et al. (1999) stated, if educators are able to "connect the use of new technology to their own teaching experiences" (p. 212). The planning framework described below focuses on these ideas.

Second, in order for educators to be willing to use multimedia technologies in the classroom, it is necessary that they feel confident in their use from a technical perspective. Hence, professional development programs need to provide opportunities for developing basic computer competencies necessary for developing confidence in using technology as a normal part of teaching activities. Again, it is stressed that learning technical aspects must occur not in isolation of educators' teaching contexts, but rather in parallel with and integrated with pedagogical development. In this way, acquisition of technical knowledge is appropriate to the needs of the educators and is thus more likely to be relevant.

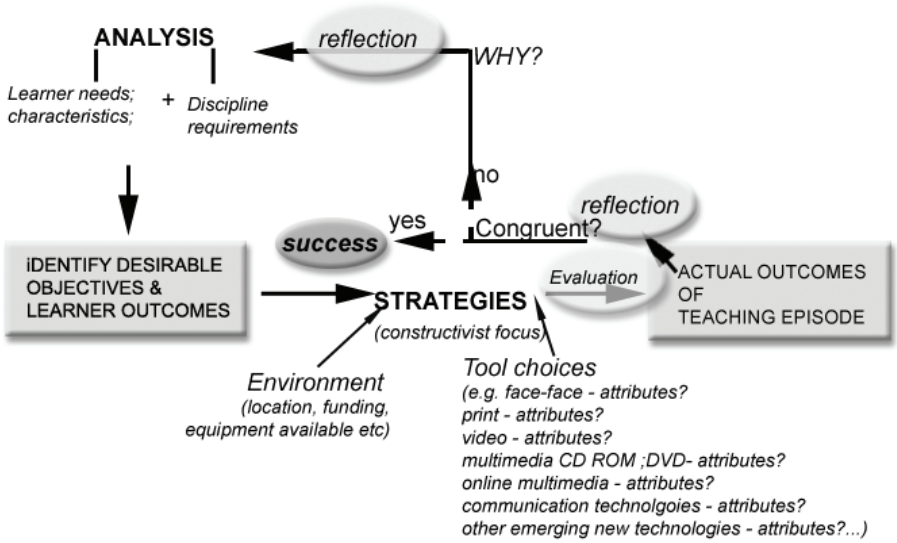
A Planning Framework

The five key guidelines above, together with issues discussed in this paper, can be embodied in a framework that provides a more concrete approach to curriculum planning conducive to the integrated use of multimedia technologies. The framework may be used to guide educator development (as has been done by the author) or may be useful as a guide for individual educators as they plan for multimedia technology use. The framework aims to highlight the use of multimedia technologies as part of the set of tools that is available for educators in executing teaching and learning strategies.

The framework is thus directed toward appropriate and judicious use of multimedia technologies. It also encourages educators to consider the attributes of them and then consider how to exploit those technologies for producing more meaningful and varied learning experiences; in so doing, allowing technology use to be an integral part of "knowledge spaces" which "allow users to explore as they wish" (Brown, 1997).

Consistent with learner-centered approaches, the process begins with an analysis of learner characteristics and of learner needs in relation to the content that is to be taught. In defining learner needs, the demands of the content must also be taken into account. As stated in Jamieson (1999), "The content of student learning (what is taught) logically precedes the method of teaching con-

Figure 1. Framework for appropriate integration of multimedia technologies into the learning environment. Environment attributes include human resources, financial resources, and other infrastructure and institutional limitations. Multimedia and other emerging multimedia technologies form part of the set of tool choices that the educator might choose on the basis that the attributes of the chosen tool(s) best fits with the learning context and desired outcomes.



tent…without content there is no teaching method" (p. 2). On the basis of this analysis, desired learner outcomes and objectives are identified.

In formulating teaching and learning strategies, the framework demands that the choice of tools be an informed choice based on integrated knowledge of strategy, learner needs, content requirements, environmental constraints (location, available equipment, funding, etc.), and tool attributes. Thus, the aim of technology integration more naturally precipitates from using the framework.

The fundamental view expressed by the model is that multimedia technologies and other emerging technologies are part of a tool set that, along with other available options (face-to-face teaching, print, etc.), are available choices for strategy implementation. Inherent in the presented framework is the philosophy that learning about multimedia technologies is an exercise in identifying the attributes of that technology and, at the same time, considering those attributes in terms of usefulness in the curriculum (Table 2). This approach addresses the problem of the "blanket approach" to multimedia technologies use that sometimes arises when the hype surrounding a new technology emphasizes the technology itself rather than learning as the primary concern. The proposed framework does not exclude the use of more traditional approaches or tools such as print, etc., if they are deemed appropriate to the learning situation.

It is also worth noting that the framework encourages evaluation of strategy outcomes and reflection on existing as well as new strategies. Consideration of the use of multimedia technologies occurs with the goal of modifying or replacing existing strategies that, upon reflection, are considered ineffective. This is considered an important characteristic of the framework for two reasons:

Table 2. Some common tool choices for teaching and learning and their main advantages and disadvantages

Tool	**Advantages**	**Disadvantages**
Textbook and other print materials	Portable, inexpensive, simple, "low-tech," easy to use, preorganized quantities of information, accessible without special equipment, can be inexpensive, most educators familiar with this medium and have production expertise	Become outdated, cannot update easily, static information presentation, no interaction possibilities
Video	Motivational, sound and images to convey information, readily available, easy to use, inexpensive	Linear information presentation, multiple copies for student access at home can be problematic/expensive, video production can be expensive and time consuming, requires VCR access and display mechanism
Face-to-face teaching	Can respond to needs of students dynamically, can be used to promote discussion, collaborative learning, enables clarification and analysis of information	No flexibility for students in terms of attendance, access limited to on campus
Multimedia CD ROM	Can convey information using video, audio, sound and text; once produced, inexpensive to replicate for student access; option for nonlinear information presentation, so learners are able to explore at their own pace, forming their own pathways; high interactive learning potential	Costly both in terms of time and money to produce; production requires a high level of technical expertise; software and content become outdated—cannot update easily without undergoing another development and production run
World Wide Web—Web sites and related Internet technologies	Increasingly supporting multimodal presentation—text, images, sound, video, and higher levels of interactive possibilities; access to up-to-date information; potential for collaborative learning with learners in multiple locations (e.g., chat, videoconferencing); potential for anytime, anyplace; highly motivational; updating of information relatively easy Wealth of up-to-date information available along with nonlinear nature, interactivity and multimodal presentation can support discovery orientated strategies	Requires costly technical infrastructure (networks, workstations, video conferencing facilities) Development of own online materials: complex requiring expertise; can be costly and time-consuming; involves a high level of commitment Updating Web materials can be difficult/frustrating if not technically competent to some degree Sophistication of Web materials available to students is limited by access factors such as bandwidth, modem capabilities Not all educators are familiar with/comfortable with the new media technologies—steep learning curve both in technical understanding and implementation strategies; lack of awareness of these issues is one of the greatest pitfalls in adopting multimedia technologies; **as technology capabilities increase, so do complexity, commitment required, and the potential of "things not working"**

1. It promotes the perspective that multimedia technologies are implemented with the primary goal of pedagogical change (thus helping to dispel the idea of a simple translation approach to technology adoption).
2. This encourages educators to draw on prior knowledge and experiences with prior teaching and make stronger connections between these experiences and the use of the technology (Bennet, Priest, & Macpherson, 1999). This is an important aspect of professional development efforts aimed at facilitating technology adoption for two reasons: perceptions of relevance are increased; and feelings of inadequacy that may be experienced by educators in dealing with new technology are minimized (Torrisi & Davis, 2000).

Reflective practice forms the cornerstone of the framework and is consistent with the notion of an evolutionary approach to technology integration. Execution of the strategy must be followed by a careful analysis of congruency of intended and actual outcomes. This analysis may involve formative and summative evaluation methods as well as personal reflection. The key question now becomes the following: Are the desired/anticipated outcomes congruent with actual outcomes? If they were, then the strategy is a success. Any discrepancies, however, need to be considered in the light of reflection of the process—Why did the discrepancies occur? In what ways might the strategy be changed or improved? Were the tool choices appropriate? The approach thus leads to a cycle of reflection followed by modified implementation followed again by reflection. Reflection on the process is not limited to assessment of whether outcomes were satisfactory, but rather encourages inspection of each stage of the planning process in order to identify shortcomings in either analysis or strategy. Aside from facilitating better technology integration into the curriculum, this approach may assist in overcoming some of the resistance to technology adoption, in that technology adoption becomes motivated by the need to improve practice.

The brief case study below illustrates an application of the framework and the beliefs expressed in this chapter.

A Case Study

The following case study is for a course in human services at tertiary level study. The case study summarized in Table 3 illustrates the key tenet of the framework described above that requires decision making regarding the tool choices for strategy implementation to be based on consideration of learner characteristics, desired learner outcomes, discipline requirements, and environmental considerations.

Resulting Subject Form

Given the adequate technical infrastructure, a subject Web site is used as the principal organizing medium for the subject and also as the primary means of preparation before engaging in face-to-face contact time. The Web site outlines weekly schedules and presents appropriate simulations and interactive exercises to introduce learners to course content and begin the process of self-reflection on beliefs and practices. The potential of multimedia-based Web sites to be used for more dynamic and engaging presentation of content prior to class time is exploited. Interactive case scenarios are presented via the Web site where they encourage students to explore their existing knowledge. This will "free-up" face-to-face class time for more valuable, deeper discussions rather than pure content presentation and initial reflection. Participation in discussion is important in helping students to analyze their own assumptions and in exposing them to the feelings and thoughts of others. The sharing of experiences, particularly after practical placements, is an important mechanism in this subject. Face-to-face contact is seen as an important tool for achieving

Table 3. Based on the planning framework described, this table illustrates how, for a tertiary-level human services course, decision making about tool choices for implementing strategies satisfies the constraints and demands of environment, learner characteristics, discipline requirements, and desired outcomes as well as addresses issues with previously used strategies. From the perspective of multimedia technology use, multimedia technologies are exploited in terms of attributes that will satisfy these demands and constraints. This facilitates appropriate and integrated technology use.

Tool choice (indicated by *) / **Issue/consideration**	Multimedia-based Web site	Web communications technologies	Print	video	Face-to-face
Environment: Good technical infrastructure (computer laboratories and Internet access) allowing for on-campus access outside working hours; the majority of students have computer and Internet access at home; regular on-campus contact time is also scheduled	*	*		*	*
Learner characteristics Mostly mature (nonschool learners) learners, with a high proportion of learners in full-time employment, with a cross section of abilities, backgrounds, and experiences; on-campus attendance is sometimes problematic	*	*	*		
Desired learner outcomes • "Challenge their own assumptions"	*	*			*
• "Analyze the thinking underlying practice"		*			*
• "Connect theoretical material with their own life experiences"	*	*			*

continued on following page

Table 3. continued

Tool choice (indicated by *) / **Issue/consideration**	Multimedia-based Web site	Web communications technologies	Print	video	Face-to-face
• "Think through how values can be incorporated into a real-life situation"	*			*	*
Discipline requirements: Off-campus practicum sessions— need for easily portable materials and off-campus access as well as communication with peers off-campus; thinking through and changing beliefs is a core goal of the subject	*	*	*	*	*
Issues with previously used strategy relying on face-to-face contact with print materials: Students failing to engage with reading materials prior to class, so much of valuable face-to-face contact time is used for delivery of content rather than active discussion Some students miss out on classes on occasion, because they are working or have other commitments	* *Web multimedia materials More interactive and stimulating— encourage more active involvement with content*	*			

learner outcomes that focus on analysis of beliefs and practices.

The Web site also enables students to have around-the-clock access to class materials. Chat rooms are useful in enabling students to support each other and collaboratively solve problems, especially when away from campus on practicum. Support is also available from tutors at certain times of the week, during which students can log in while off campus. This is an important mechanism for helping students to connect theoretical knowledge with the experiences they are undergoing at the time. E-mail is also useful in encouraging and maintaining student–faculty contact during practical and other off-campus times.

Print materials will still be used but primarily as an easily portable reference source, especially while on practicum, rather than as a primary source of information prior to attendance at face-to-face class times.

FUTURE TRENDS

The range and nature of multimedia technologies are constantly changing. In an educational context, the challenge is to develop approaches to planning that can be used to facilitate integration of existing and future technologies. By conceptualizing the role of technologies in the learning context as a component of a set of tools, it is intended that the framework and ideas presented in this chapter be one step in the direction of "generic" planning approaches that will provide guidance to educators and those involved in their professional development in both current and future technological environments. Planning approaches need to be contextually framed so that the key focus is to exploit the attributes with the aim of providing deeper, more meaningful learning experiences that will equip students with the lifelong learning skills demanded in the present and the future.

Evidently, with the dynamic nature of multimedia technologies, there will always remain a need for ongoing professional development that will present opportunities for educators to investigate the attributes of multimedia technologies as they emerge in terms of usefulness for their particular teaching contexts. From this perspective, ongoing research focusing on which technologies are being used in what contexts and what results are being obtained becomes important. Such research will highlight the attributes of the technology that are worth exploiting and for what purposes and could result in models of implementation so that educators could draw upon one another's experiences.

CONCLUSIONS

The framework and ideas presented in this chapter precipitated from concern about the ineffective and often inappropriate use of multimedia and associated technologies in learning contexts.

The fundamental belief expressed in this chapter is that effective use of multimedia and other technologies in teaching and learning environments occurs when multimedia technologies are integrated fully and appropriately into the curriculum. The primary goal for integrating multimedia and associated technologies into the curriculum is to provide for a learning environment that espouses more meaningful and deeper learning.

It is advocated throughout this chapter that multimedia and associated technologies are considered as part of a tool set available for strategy implementation. If, how, and when to integrate technologies are decided by taking into account constraints and conditions imposed by the environment, learner characteristics, desired learning outcomes, and the nature of the content, and by reflecting on success or otherwise of previously used teaching practices. Also highlighted is the important role of reflective practice. Another key

theme is the need to foster the view that technology integration is an evolutionary, transformative process rather than an exercise in translation of strategies to another medium. The five guidelines for multimedia technology use and the planning framework presented in this chapter incorporate these views.

The dynamic, rapidly evolving technological environment characteristic of the present and the future represents ongoing challenges for educators striving to make use of these new tools to the best advantage for a more effective learning environment and more meaningful learning outcomes. Despite the dynamic nature of technical environments, it is the author's belief that there is at least one constant premise upon which educator development aimed at multimedia technology integration efforts can develop—that is that change in practice is inextricably linked with successful integration of multimedia technologies in teaching and learning contexts. Nurturing the acceptance of this premise needs to be a matter of priority in current and future educator development efforts in the area of educational application of technologies.

Chapter 8.7
Planning Effective Multimedia Instruction

ABSTRACT

Multimedia benefits students learning in many different ways. There are so many things that students can do and learn because of the variety of instructional media that is available for their use. The use of instructional multimedia increases an instructor's ability to propose and execute teaching strategies that come with a multiplicity of learning styles. Therefore, there are a myriad of reasons why teachers use these resources both as a teaching tool and a teaching resource. Several strategies can be implemented so that teachers have opportunities to become skillful in attaining technological fluency. This chapter reviews the trends and issues of today's multimedia education, and attempts to provide strategies and guidelines for planning multimedia instruction. The effective use of pedagogical design principles with appropriate multimedia can permit greater individualization, which in turn fosters improved learning, greater learner satisfaction, and higher retention rates.

INTRODUCTION

Technological capabilities are growing in today's world by leaps and bounds. Over the past few decades, there have been remarkable advances in

computer and interactive media technology. As a result, there has been a tremendous increase of investment in school technology and media use. Teachers are also being asked to learn the skills and techniques required to use computers and instructional media in classrooms.

The diverse characteristics of different multimedia and the capabilities that they provide for learning have direct implications on the design of multimedia strategies and materials (Fahy, 2005). Goldman and Torrisi-Steele (2005) state that "the essential value of interactive multimedia technologies is that they can be used effectively to empower students to take a more pro-active role in acquiring, analyzing, and synthesizing information" (p. 191). Although today's technologies make possible the use of multimedia by helping to move learning beyond a primarily text-based and linear arena into the cyclical world of sights, sounds, creativity, and interactivity, the challenge is whether the essence of multimedia can be integrated into an essential discipline (Gonzalez, Cranitch, & Jo, 2000). If some pedagogical design principles and appropriate media are used effectively, multimedia can permit greater individualization, in turn fostering improved learning, learner satisfaction, and retention rates (Fahy, 2005).

This chapter discusses the definition of "multimedia," including the trends and issues of today's teaching and learning. The goal is to review the benefit of using multimedia instruction, and to attempt to provide some strategies and guidelines for planning multimedia instruction. By outlining some fundamental issues and considerations affecting implementation of multimedia, the chapter discusses some challenges and impacts of multimedia instruction when teachers are ready to move from simpler to more complex combinations of media for teaching. Additional examples drawn from literature are also included to discuss the use of multimedia in education and the strategies of planning effective instruction.

TRENDS AND ISSUES

The rise in the usage of technology is bringing about rapid change in the educational environment. In keeping with this changing environment, teachers need to discover ways to broaden their range of teaching methods so that they can produce more effective learners. Emerging trends including individualized learning, cooperative learning, collaboration learning, learner center approach, and assessment portfolio have been playing an important role in education. Research indicates the importance of increased technology integration in the classroom. When using interactive technology, students not only learn more quickly and enjoyably, but also learn the much needed life skill of learning how to learn (Vogel & Klassen, 2001). However, many educators today are facing the issue of integrating technology into their instruction (Wang & Speaker, 2002).

Technology continues to change dramatically. Although it may be recognized by educators that multimedia technologies have the potential to offer new and improved learning opportunities, many educators fail to realize this potential (Torrisi-Steele, 2005). Similarly, Kaufman (2002) also summarizes that most teachers have been taking advantage of technology's mass storage capacities, but they have not exploited its greater potential to motivate knowledge construction and facilitate problem solving. As a result, a number of educators using multimedia technologies in their learning environments are mainly limiting its use to a tool for data access, communications, and administration (Conlon & Simpson, 2003) rather than a tool for integrating curriculum (Torrisi-Steele, 2005). This lack of true integration results in minimal change in both pedagogical strategies and learning environment (Tearle, Dillon, & Davis, 1999).

In addition, failure to implement effective technology integration could be associated with teachers' technology skills and attitude as well. As Speaker (2004) concludes, student use and perception of a multimedia educational

experience is highly dependent on the attitude of the teachers and their ability to provide useful contextual information in a format that meets the criteria of relevancy and interactivity in a student-centered approach. However, research (Torrisi-Steele, 2005) shows that teachers are generally unprepared for the technology changes, and often lack the skills as well as technical and pedagogical knowledge to effectively implement those technologies in their learning environments. As a result, students' classroom practice may not meet student expectation especially in the area of integration and use of multimedia (Speaker, 2004) because today's students are often far more skilled at using digital media than most of their teachers. Torrisi-Steele states (2005), "The effective integration of multimedia in the curriculum depends not on the technology itself but rather on educators' knowledge, assumptions, and perceptions" (p. 26). Therefore, teachers should develop a desire to integrate technology into their classroom, and also need careful plans for multimedia instructions.

WHAT IS MULTIMEDIA?

The term "multimedia" means different things to different people; however, definitions of multimedia tend to agree in substance (Fahy, 2005). Fahy (2005) states that "the term "multimedia" refers to the provision of various audio and video elements in teaching and training materials" (p. 3). When Ivers and Barron (2002) define multimedia as "the use of several media to present information" (p. 2), Mayer (2001) views multimedia as "the presentation of material using both words and pictures" (p. 2). To Peck (as cited in Speaker, 2004) multimedia is "as a computer controlled combination of two or more media types, to effectively create a sequence of events that will communicate an idea visually with both sound and visual support" (p. 242). Not only do Roblyer and Schwier (2003) define multimedia as "a computer system or computer system product that incorporates text, sounds, pictures/graphics, and/or audio" (p. 329), but they also imply its purpose as one of "communicating information."

Due to the growing delivery of media by the computer and the merging of increasingly powerful computer-based authoring tools with Internet connectivity, it seems that the term "multimedia" is now firmly associated with computer-based delivery. Although the term has not always been associated with computers (Roblyer & Schwier, 2003), Gonzalez et al. (2000) write that "multimedia cannot be experienced without the technology because it is the technology that creates the experience" (¶ 9). Therefore, Gayeski (1993) defines computer-based multimedia as "a class of computer-driven interactive communications systems which create, store, transmit, and retrieve textual, graphical and auditory networks of information" (p. 4). In other words, computer-based multimedia involves the computer presentation of multiple media formats (e.g., text, pictures, sounds, video, etc.) to convey information in a linear or nonlinear format (Ivers & Barron, 2002).

With an increased availability of digital information options, today's commonly accepted definition views multimedia as a combination of different media (i.e., text, pictures, sounds, video, animations, etc.) used to present multimodal information, in conjunction with computer technology. However, the majority of definitions, in general, only take into consideration the basic instructional delivery system. These definitions may be less meaningful, particularly in education, if multimedia cannot be incorporated with the way people learn and work. Because multimedia enables learners to engage the greatest number of the senses, multimedia can be a very powerful pedagogical tool if teachers can focus on the foundation for learning. By integrating multimedia to teaching and learning, students can work with increased information in more creative ways than ever before to make the knowledge more applicable and retainable.

MULTIMEDIA LEARNING

The capability of multimedia provides teachers with an array of learning pathways to offer students. According to Biggs (1999), learning is a way of interacting with the world. In other words, learning takes place through the active construction of knowledge by the interaction between information received through different channels and existing knowledge stored in the learner's long-term memory (Christie & Collyer, 2005). Wild (1996) describes what is successful in learning is to describe successful interactions between learner, context, and instruction. The potential of multimedia is to foster the level of interactivity as a form of learning, and to offer many possibilities for enriching the knowledge or information for learners. As Zhang (2005) concludes, multimedia instruction along with high levels of interaction can help maximize learners' ability to retain information and learner engagement.

Benefit of Multimedia Instruction

There are many benefits of interactive multimedia instruction. The first is compliance with the requirements of No Child Left Behind Act of 2001 (NCLB). The challenges of NCLB no longer allow schools the luxury of viewing technology as an add-on function at the periphery of instruction, a curriculum enhancement, or as an occasional frill that makes learning more fun; instead, schools and particularly teachers must adopt and embrace technology so that it restructures the way learning is managed and administrated (Tetreault, 2005). The increased control of pace, sequence, difficulty, content, and/or style of the instructional media presentations allows learning to be customized to each student's distinctive needs. Teachers can thus ensure at least some progress of the student. The students, on the other hand, can better comprehend the level of skill and knowledge that is required by the work, and also progress at their own pace, allowing for greater achievement by those who are mentally ready to move ahead. This is an important step based on the NCLB Act, which calls for the Secretary of Education to "conduct a rigorous, independent, long-term evaluation of the impact of educational technology on student achievement using scientifically based research methods and control conditions" (as cited in Means & Haertel, 2004, p. 9). This call for action is to evaluate the effects of the investment of bringing instructional media into the classroom. If the Education Secretary finds positive results in the use of instructional media in the classroom, then it shows that the national investment has indeed been a worthwhile venture.

Another benefit of media-based instruction is the reduction of the time required to reach instructional objectives. If teachers do not have to spend instructional time repeating material that most of the students already know, then the learning of new material could occur more quickly. Since media-based instruction also keeps students interested and more involved in educational material, this allows for wiser use of both their time as well as the teacher's time.

Multimedia instruction also provides a stimulus for learning by increasing social interactions and cooperation. Hoyles (1994) reports that there is a relationship between students involved in multimedia-based environment where the collaboration was seen to lead to higher-order thinking, hypothesis formation, and reflection. A Mevarech and Light (1992) report on a review of studies, which investigated the potential of multimedia-based learning environment to enhance group work provides convincing evidence of the value of group work and collaboration, and its positive impact on productive learner dialogue, interchange of ideas, and negotiation of solutions.

With one-to-one interaction being regarded as an educational ideal, efforts to realize this through information technology have included intelligent tutoring systems and telementoring. These intelligent tutoring systems, like their human counterparts, are fully expected to respond

flexibly to student inputs so as to optimize progress toward a learning objective. It involves one-to-one interchanges between tutor and student, typically relying on e-mail exchanges between a student and experts in that field. The program's success is extremely dependent on the match between the mentor and the student (Kovalchick & Dawson, 2004).

New knowledge media such as video productions, simulations, and microworlds extend the range of experiences and concepts that can be brought into school. For example, field trips are regarded as classic ways to explore worlds not easily represented through school-based instructional materials. With today's virtual reality, students can experience an interactive "field trip" without leaving their classroom. In addition, providing multimedia instruction has been found to have a positive impact on students' perceptions of teachers. For example, teachers who use presentation visuals are judged to be better prepared, more concise, professional, clearer, credible, and interesting (Vogel & Klassen, 2001). Also, multimedia technology can enable teachers to work together to share material and complement each other's expertise, thereby adding value to education (Alavi, Yoo, & Vogel, 1997). The use of multimedia also links students and classes together as well as enhances the ability of government and business experts to participate in education.

Use of Multimedia Instruction

The strength of multimedia instruction lies in its ability to adapt to students' individual differences and capabilities of controlling the learning path. With the new trend in education that emphasizes the importance of learning *with* technology instead of learning *from* technology (Jonassen, Howland, Moore, & Marra, 2003), the accessibility of multimedia technologies has presented an array of choices to instructors these days. For example, there are many ways that computer use can and does benefit students in their learning. The first major instructional use of computers and software programs was simply for drill and practice. This was seen as a beneficial use for students who need extra or special practice when the teacher just did not have enough time to perform this task.

Another use is computer-assisted instruction. This requires more advanced instructional programming than drill and practice programs. This type of software provides concepts and content in a straightforward approach. As Chipman (2003) indicates, "The computer offers management of the student's study efforts through pacing and interspersed questions" (p. 39). These programs can vary from simple to more sophisticated where the computer may respond differentially to student responses with preprogrammed responses of its own.

An additional use, which is also quite popular, is the use of simulations. These are safe environments and are easily accessible to students. "Simulations make it possible to experience an approximation of phenomena that otherwise might merely be talked about" (Chipman, 2003, p. 40). Simulations open new possibilities in teaching and permit students to practice events or phenomena that might be too hazardous or too intricate to duplicate, but to be effective, they must be integrated with a larger curricular context. For example, in a science class, if students are learning the body parts of frogs, students can use a computer program to simulate a frog dissection, instead of cutting up an actual frog. This simulation may not give students the hand-on experience; however, it is much cheaper and it can be used over and over. It is also more flexible because the frog can be reassembled by the program, and the simulation can avoid sacrificing a real frog.

Another popular use today is streaming video. It revolutionizes the way visual content is used in the classroom for clear demonstrations of proficient performance. It also provides more learning potential that the use of VCR's, and empowers teachers and students to study a broader range of topics with higher retention and comprehension,

which is a key to maximizing student achievement (Holland, 2005). With streaming video, students can now watch a lecture, tutorial, or presentation online via normal modem, and at the same time review the corresponding documents or materials in a highly compressed, Web browser accessible format.

Other uses that are applicable from elementary school level and up include drill and practice software, problem-solving software, Web-based software, data analysis and reporting software, and demonstration presentation software (Bitter & Pierson, 2003). These are all tools that can and should be very valuable assets for many grade levels and subject areas. For example, presentation software such as PowerPoint allows teachers to place class materials together in a dynamic and meaningful manner. The ability to integrate sound, picture, and video into PowerPoint slides offers tremendous potential to captivate the child's attention and give the child a sense of control over the learning process that makes it more palatable (Yu & Smith, in press). Interactive applications such as the World Wide Web can be used as a main information resource for students to access any time and any where, or for the storage of instruction materials including class notes, presentation visuals, and video recordings. In addition, data analysis and reporting software such as Excel provides all the functions to manipulate numbers, takes numeric and alphanumeric format data as input to a matrix, performs matrix calculations, and produces a computed spreadsheet as the main output. For instance, students in math and finance related classes might be able to use Excel to perform predefined calculations automatically, provide statistical functions, and display charts. In some ways, it is easier to use computers over calculators since numbers are visible all of the time on the screen. Students can move gradually from using them as a super-calculator to using them for modeling or simulation. In other words, they can move from using them to ask *What is* questions to *What if* questions. Thus, they also can be used as decision-making aids.

MULTIMEDIA FOR EFFECTIVE INSTRUCTION

The term effective instruction as it is used today does not mean the same thing that it did just a few years ago. It once meant simply teaching the basics—reading, writing, and arithmetic. Now it means much more. It means not only teaching the basics, but also teaching concepts and discoveries using technological media. There are so many things that students can do and learn because of the variety of instructional media that is available to them. There are a myriad of reasons why teachers must use these resources both as a teaching tool as well as a teaching resource. One reason is because of the ever-increasing amounts of interactive instructional media resources that have become available all over the world, even in our schools. Another reason is because students today are far more technology savvy than most teachers are. Additionally, most states have added technology proficiency to their teacher licensing requirements. Because of this, policy makers, teacher educators, teachers, and school administrators must do something to ensure that all teachers are proficient in the use of instructional media as educational tools (Zhao, 2003). Teachers are responsible for creating a learning environment that emphasizes the impact of content and increases student learning (Vogel & Klassen, 2001). With the assistance of multimedia technology, demands from the teacher in a technological learning environment are increasing also. Thus, the importance of planning effective multimedia instruction is continuously growing for individual educators in primary, secondary, and other training environments.

PLANNING FOR MULTIMEDIA INSTRUCTION

The value of integrating multimedia technology into classrooms at all levels has been discussed

in many research studies in different disciplines (Agarwal & Day, 1998; Stone, 1999). Gonzalez et al. (2000) indicate that "multimedia is more than a collection of sound, images, video and animations. It is a vital, dynamic field offering new challenges, interesting problems, exciting results, and imaginative applications" (¶ 5). They point out the challenge--whether the unique essence of multimedia can be distilled into an essential discipline (Gonzalez et al., 2000). Successful technology integration involves careful evaluation of the curriculum and learning goals (Ertmer, 1999). Therefore, the following section seeks to provide some strategies and guidelines for planning multimedia instruction. The pedagogical aspects of effective instruction are the main focus in this discussion.

State Technology Standards

The first logical and practical step for multimedia instruction is to look at educational technology standards for teachers at the state level. Most states should have these standards in place as part of their blueprints or guidelines on what should be minimally taught at each grade level. These objectives provide a starting point on effectively teaching the use of technology and media to students. However, teachers should also realize the need to incorporate these strategies into all subject matter and not treat it as a separate entity. They should also remember that these are minimal goals and that they can and should go further in their endeavor to use a variety of media to benefit them in teaching and students in learning.

Design and Development Principles

The quality of the learning experience depends considerably on the design and presentation of instructional materials (Sanders & Morrison-Shetlar, 2001). A number of studies provide principles that can guide teachers in the design and development of multimedia instruction. Mayer's (2001) work is one such example. He reveals that successful learning requires students to perform five actions, with direct implications on the design of effective multimedia instruction:

- Select relevant words from the presented text or narration.
- Select relevant images from the presented illustrations.
- Organize the selected words into a coherent verbal representation.
- Organize selected images into a coherent visual representation.
- Integrate the visual and verbal representations with prior knowledge (p. 53).

In order to guide the design of multimedia instruction, Mayer (2001) articulates seven useful principles that can help students to achieve greater retention.

1. **Multimedia principle:** Students learn better from words and pictures than from words alone.
2. **Spatial contiguity principle:** Students learn better when corresponding words and pictures are presented near rather than far from each other on the page or screen.
3. **Temporal contiguity principle:** Students learn better when corresponding words and pictures are presented simultaneously rather than successively.
4. **Coherence principle:** Students learn better when extraneous words, pictures, and sounds are excluded rather than included.
5. **Modality principle:** Students learn better from animation and narration than from animation and on-screen text.
6. **Redundancy principle:** Students learn better from animation and narration than from animation, narration, and on-screen text.
7. **Individual differences principle:** Design effects are stronger for low-knowledge learners than for high-knowledge learners

> and for high-spatial learners rather than for low-spatial learners (p. 184).

Learners are the core in the realm of teaching and learning. Since successful interaction design that engages learners in exploring knowledge and experiences is the result of careful analysis of the learner and of the learning outcomes (Goldman & Torris-Steele, 2005), Fardouly (as cited in Goldman et al., 2005) provides some questions to guide successful interaction design while constructing multimedia interactivities:

- Who are the learners? What do they need or want to learn? In what environments will the learning be applied, and what do they already know?
- What is the teacher trying to achieve with the instruction? Clearly define goals and objectives and relevant content.
- What skills, attitudes and knowledge are you trying to develop?
- How will content be structured?
- What strategies might be used?

These examples of design principles may enhance learners' learning experience and maximize the potential of multimedia technologies.

Educational Theories-Constructivism

Leidner and Jarvenpaa (1995) categorize learning models into several categories: *objectivism, constructivism, collaborative learning, cognitive information processing,* and *socioculturism*. Among them, the leading theory of today's learning is constructivism, which is the idea that learning actually occurs when learners actively try to understand material that is presented to them. They engage in constructivist learning by deeply and actively processing the material that is to be learned in an attempt to understand it. This process can also be called knowledge construction because learners create their own knowledge, apply, and coordinate it to their own cognitive processes while learning. This learning is also traditionally known as meaningful learning or learning by understanding (Mayer, 2003).

The constructivist view of teaching and learning is a commonly accepted framework for developing appropriate strategies for designing multimedia learning environments in ways, which will promote student-centered learning environments (Goldman & Torrisi-Steele, 2002). According to Savery and Duffy (1996), effective instructional design of multimedia interactivities may be based on eight constructivist principles. They are:

- Anchor all learning activities to a larger task or problem
- Support the learner in developing ownership for the overall problem or task
- Design an authentic task
- Design the task and learning environment to reflect the complexity of the environment that students should be able to function in at the end of learning
- Give the learner ownership of the process used to develop a solution
- Design the learning environment to support and challenge the learner's thinking
- Encourage testing ideas against alternative views and alternative contexts
- Provide opportunity for, and support reflection on, both the content learned, and the learning process itself (p. 3)

The concept of constructivist learning does indeed have important implications for the use of a variety of interactive instructional multimedia. It is aimed at fostering and guiding learning and activating cognitive processing that leads to understanding. "Under this conception of learning, instructional technology should serve as a cognitive guide to help learners on authentic academic tasks-such as comprehending a text, solving challenging

mathematics problem, or conducting a scientific experiment." (Mayer, 2003, p. 128)

Learning Styles

Learning styles are also a well-known area impact on today's technology-based instruction. As Kovalchick et al. (2004) state, "Learning styles are the diverse ways in which people take in, process, and understand information" (p. 418).

It is of importance to be aware of different learning styles possessed by the learners. Litchfield (1993) indicates, "…matching learning style with design of instruction was important for both achievement and positive attitudes" (p. 5). As educators, we need to know that one size does not fit all. One learner might learn best in a cooperative learning environment while the other may achieve similar learning outcome through self-study (Marlow, 2003). This does not at all mean that the teacher has to have classroom materials tailor-made just to satisfy one or two persons' special needs. The educator should, however, be sensible and flexible to different individuals, and include a variety of methods to account for different learning styles. The use of interactive instructional media in education increases an instructor's ability to propose and execute teaching strategies that cater to a variety of learning styles. The use of multimedia facilitates learning by providing a unique opportunity to notice and adjust to the differences in every person. The use of computer-mediated communications tools like e-mail, discussion boards, and virtual chat provide many opportunities for interaction collaboration and discussion inside as well as outside of the classroom (Kovalchick et al., 2004). Teachers can use interactive media to develop and deliver instruction to a variety of learners with diverse learning styles. E-learning, synchronous or asynchronous, that is conducted over the Internet, intranet, extranet, or other Internet-based technology is another growing trend in schools today that takes learning styles into account (Abram, 2005).

Using a variety of educational media also provides a stage upon which numerous instructional approaches can be developed. This fact relates back to Howard Gardner's theory of multiple intelligences. Gardner believed that each person has a different intellectual composition made up of verbal-linguistic (speaking, writing, and reading), mathematical-logical (reasoning skills), musical, visual-spatial, bodily kinesthetic, interpersonal, intrapersonal, naturalistic, and existential skills. People possess all the intelligences in varying

Figure 1. Examples of an interactive event at each functional level of interaction

	Confirmation	*Pacing*	*Navigation*	*Inquiry*	*Elaboration*
Reactive	Learner matches answer given by system	Learner turns page when prompted	Learner selects choice from a menu	Learner uses "help" menu	Learner reviews a concept map
Proactive	Learner requests test when offered	Learner requests an abbreviated version of instruction	Learner defines unique path through instruction	Learner searches text using keywords	Learner generates a concept map of the instruction
Mutual	System adapts to progress of learner and learner may challenge assessment	System adapts speed of presentation to the speed of the learner	System advises learner about patterns of choices being made during instruction	System suggests productive questions for the learner to ask given previous choices	System constructs an example based on learner input, and revises it as learner adds information

amounts and they may employ each one separately or jointly, depending on the learning situation. The variety of interactive media that we are provided with today (such as power point, e-learning, streaming video, the WWW, etc.) can easily be used to correspond with each individual's learning style and multiple intelligence area.

Meaningful Content and Interaction

Research (Esquivel, 1995) has shown that students enjoy the instructions related to real life events. Multimedia learning can support instruction that is contextually relevant, interactive, and meets the needs of the individual learner (Speaker, 2004). Multimedia can be made challenging and varying in degree of difficulty, yet the content should be relevant to student's study (Marlow, 2003). Adding adequate numbers of audios, visuals, and texts will aid successful knowledge construction if the instructional designer has taken the curriculum and learner's ability level into serious consideration.

The different multimedia instructions can emphasize different types of interaction. Schwier (1993) categorizes interaction as *reactive, proactive,* or *mutual* depending upon the level of engagement experienced by the learner. Hannafin (1989) identifies five functions interaction can serve in independent learning materials. They are *confirmation, pacing, inquiry, navigation,* and *elaboration.* Each function is expressed differently during instruction, depending on the level of interaction, and Schwier (1993, p. 168) provides one example of interaction obtained at each functional level of the taxonomy (see Figure 1).

Multimedia instruction needs to provide meaningful content for student learning. Teachers need to provide content, which makes sense to the student. Effective learning relies on meaningful interactions between content and learners. Meaningful interactions require the learner to access that meaningful knowledge in order to relate it to new information (Zazelenchuk, 1997). As a result, instructors can help learners access the appropriate knowledge and integrate it with the new information being presented by designing meaningful content and providing the right interactions.

Learner Control

The perception of learner control is another important element. Doherty (1998) refers to learner control as the level of self-determination that the learner has in making decisions about his or her learning, and more specifically defines it as "the degree to which individuals control the path, pace, and/or contingencies of instruction" (¶ 3). Lepper (1985) indicates that learner control may increase feelings of competence, self-determination, and intrinsic interest. Since multimedia can help present information in a nonlinear or random access format, the students can not only select what information to access and how to sequence the information in a manner that is meaningful to them (Lawless & Brown, 1997), but also make decisions about their own pacing and sequencing and follow through the interactive material during studying sessions (Sims & Hedberg, 1995).

Kinzie (1990) indicates that "exercising control over one's learning can be in itself a valuable educational experience" (p. 6). Lawless & Brown (1997) emphasize that "learners within a multimedia environment must not only understand the information presented, but must also be able to identify what information will further enhance understanding and how to access this information" (p. 121). Literature (Ross & Morrison, 1988) reveals that allowing learners to select text density and problem themes can have a positive effect on both performance and the perception of learner control. In addition, allowing the users free access to information may meet the needs of the learner and also positively impact attitudes about using the medium, or allowing the students to follow a specified path of information, choosing to revisit the information or to proceed onto the next

step may be more beneficial (Lawless & Brown, 1997).

Lawless and Brown (1997) indicate that learner control can positively influence effectiveness and efficiency of learning. They summarize five basic author imposed control levels, including *browsing, searching, connecting, collecting,* and *generating.* They also indicate that these are hierarchically ordered on the basis of learner control and level of learner interaction. For example, *browsing* offers the least learner control and is least interactive, because generally learners browsing through a multimedia environment lack specific intention or a defined goal, when *generating* allows students to go beyond controlling and sequencing the instruction to contribute to the instructional database.

While some learner control can motivate students, too much can be confusing (as cited in Litchfield, 1993). Learner characteristics such as prior knowledge and attitude can have a profound effect on knowledge acquisition in learner-controlled environments (as cited in Lawless et al., 1997). Snow (1980) indicates, "Learner control cannot be expected to overcome the persistent fact that individual characteristics not under the control of the individual will determine to a significant extent what and how much that individual will learn in a given instruction setting" (pp. 152-153). Hazen (1985) suggests that the optimal degree of learner control should be determined by learner characteristics, the nature of the content, and the complexity of the learning task.

Some students may not be able to make effective use of learner control. In order to help learners make decisions over their own learning and build effective learning strategies, literature (Jo, 1993) concludes the following recommendations for learner control to be integrated into the design of instruction:

- Control options should be clearly labeled to help learners use control options effectively.
- Immediate feedback, continuous advice on learners' on-going progress, and summaries of their uses of control options should be presented to help learners make "informed decisions" about their own learning.
- Basic requirement over important instructional components should be provided to learners in order to assure that they do not bypass the components.
- Prior to instruction, pre-training should be provided to learners to help them become familiar with the novel learning system with control options, perform conscious cognitive information processing, and understand objectives, procedures and values involved in building their own learning strategies (as cited in Jo, 1993).

CONCLUSION

Horng, Hong, Chanlin, Chang, and Chu (2005) reveal that multimedia use is one of the most important strategies of creative instructions. Multimedia not only has enormous potential for enhancing the learning, but also provides learners with varying levels of interactivity. To benefit from multimedia technology, teachers have to actively engage students in the presentation of information, and not just let the students become passive observers. Because teachers are the key to providing quality computer and interactive instructional media experiences for young children, the instructional materials they develop have to make the best use of multimedia technology within the framework of educational theories and learning principles. However, like Lawless et al. (1997) emphasize, "We have to be more cautious not to make the instructional system fit the technology but make the technology fit the instructional systems and formats that have been demonstrated to be effective. Technology is not effective learning in and of itself, but only provides a forum for effective learning" (p. 127-128).

Although today's multimedia technology provides exciting possibilities for creating quality learning experience and outcome, there will only be a minimal change impact if multimedia cannot be integrated with curriculum. Good teaching and real learning have thus become more important. Biggs (1999) states, "there is no single all-purpose best method of teaching. Teaching is individual" (p. 2). Multimedia can permit greater individualization if learning principles and strategies can be applied effectively. As the use of multimedia grows in education, multimedia pedagogical strategies will have a profound impact on how educators approach and engage students in the process of teaching and learning. This chapter discusses these principles and strategies for planning multimedia instruction, and intends to present them as guidelines for teachers using multimedia instructions in the classroom. The demand for making good use of multimedia to the best advantage for more effective and meaningful learning is continuously challenging educators teaching in such a rapidly evolving technological environment. Despite the dynamic nature of environment, educators' efforts of planning multimedia technology integration should be still ongoing and encouraging because the educator's role does not just stop at the planning multimedia instructions.

KEY TERMS

Asynchronous: A method of two-way transmitting data in which the parties present in the different time and space. An example of asynchronous communication is e-mail.

Computer-Assisted Instruction (CAI): Primarily refer to the use of computer(s) to present instruction to students. CAI is designed to help students learn new materials through interacting with the computer and students can progress learning with their own speed.

E-Learning: E-Learning is the use of network technology (broadly, the "Internet") to design, deliver, select, administer, and extend learning. Components of Internet-enabled learning can include content delivery in multiple formats, management of the learning experience, and a networked community of learners, content developers and experts.

Multimedia: The use of innovated technology to integrate text, graphics, animation, video and audio to transmit information.

Multimedia Instruction: Computer-based guidance that involves the use of diverse types of media, such as presentations, Web-based guides and online tutorials, in order to convey an instructional message.

Simulation: An interactive multimedia application device intended to imitate a real life situation and permit the user to partake and experience in a risk-free environment.

Synchronous: A method of two-way transmitting data in which the parties present in the same time and space. An example of synchronous communication is a chat room.

Virtual Reality: An interactive computer-based technology that allows the user to execute/perform actions in multi-dimensional setting.

Chapter 8.8
XML Music Notation Modelling for Multimedia: MPEG–SMR

Pierfrancesco Bellini
University of Florence, Italy

ABSTRACT

The evolution of information technology has changed the use of music representation and notation in software applications, transforming and extending them from a simple visual coding model for music scores into a tool for modelling music for computer programs and electronic devices in general (e.g., keyboards), to support the exploitation of the multimedia characteristics lying behind music notation and representation. The MPEG symbolic music representation (MPEG-SMR) is a new emerging standard for modelling music notation within the MPEG multimedia framework. MPEG-SMR provides an XML-based language to model most of the music notation in terms of the visual and audio aspects, as well as music score annotations. MPEG-SMR also provides a language to define the music score formatting rules, supporting personalisation for the score visual presentation, custom symbols, and control visual rendering of the common notation symbols.

INTRODUCTION

Music in multimedia applications and frameworks is often considered only for its audible dimensions, while neglecting the important issues on the representation of the symbolic aspects. This could be due to historical cultural effects, since many popular and earlier multimedia tools are built for entertainment applications, and not focused on education, preservation, or research purposes. Music notation is an abstraction of the music. Not all performers use notations, and music notations have many different styles and forms. Currently, multimedia tools frequently use simple symbolic representations of music to represent the production of sound/music – for example, notes produced by an instrument.

Notations for the representation of music symbols have been developed over the years and ages to visually represent the pieces of information needed by a performer to play the music piece and reproduce the music as the author/composer

intended. The production of music notation scores for professional publishing on paper is one of the most traditional applications of music notation on computers (Blostein & Haken, 1991; Rader, 1996; Selfridge-Field, 1997).

The evolution of multimedia applications is accelerating relevant changes in the usages of music representation and notation in computer-based applications. Nowadays, it is no longer unusual to see music notation and modelling integrated into professional and educational music/audio applications (Bellini & Nesi, 2004; Byrd, 1984). In the past, several XML-based languages for music modelling have been proposed, including MNML (Musical Notation Markup Language), MusicML, MML (Music Markup Language), MusicXML (Good, 2001), WEDELMUSIC (http://www.wedelmusic.org) (Bellini & Nesi, 2001; Bellini, Della Santa, & Nesi, 2001), CAPXML (Capella, 2005), and so forth. Past efforts for music notation standardization were SMDL (SMDL, 1995) and NIFF (NIFF, 2005). Most of them are mainly focused on modelling the music elements to preserve and interchange the notation format and information among different applications (for editing and rendering of music scores), rather than to provide features that could support the integration of music notation with multimedia, for example, synchronisation with audiovisual and 3-D rendering, references and hyperlinks, multilingual lyrics, automatic formatting and rendering, and so forth. These features are clearly required and can be seen in tools from industrial projects, and R&D areas:

- Multimedia music for music tuition, such as VOYETRA, SMARTSCORE, PLAYPRO, MUSICALIS.
- Multimedia music for edutainment and infotainment, such as WEDELMUSIC (integrating music notation and multimedia to build and distribute multimedia-music cultural content with digital rights management), or to produce multimedia content for theatres: OPENDRAMA (http://www.iua.upf.es/mtg/opendrama/);
- Cooperative music editing, such as in MOODS (http://www.dsi.unifi.it/~moods), (Bellini, Fioravanti, & Nesi, 1999; Bellini, Nesi, & Spinu, 2002), and more recently using MAX/MSP with I-MAESTRO project (http://www.i-maestro.org).

Most of the applications mentioned are based on a multimedia music content format that is specific for each product. This is why any information exchange among the products can be so difficult, and it is strongly restricted to subsets of the notational part, for example, in MIDI. The lack of standardized symbolic music representation integrated with multimedia content results in each developer/company implementing their own solution, which may vary in efficiency, scope, features, quality, and complexity.

In this context, the MUSICNETWORK (http://www.interactivemusicnetwork.org) project began in 2002 to support a group of experts to identify a standard format for music representation for multimedia applications. The MUSICNETWORK started to work with ISO MPEG on the SMR (symbolic music representation), as described in another chapter of this book. The integration of SMR in MPEG multimedia framework, with technologies ranging from video, audio, interactivity, and digital rights management, has enabled the development of many new applications like those mentioned earlier and in Bellini, Nesi and Zoia (2005).

An overview of the MPEG-SMR standard is presented in this chapter.

MPEG SYMBOLIC MUSIC REPRESENTATION

The MPEG symbolic music representation (SMR), as specified in ISO/IEC 14496-23, is composed of three different languages:

- The Symbolic Music Extensible Format (SM-XF) to encode main score, single parts, and lyrics.
- The Symbolic Music Formatting Language (SM-FL) to customize music formatting style.
- The Symbolic Music Synchronization Information (SM-SI) that is used to provide synchronization information with the multimedia scene.

Figure 1 shows the relationships among the SMR data in the event of a music score with three parts, and how the SMR data is used by an MPEG-4 player to produce a synchronized multimedia presentation. Both SM-XF and SM-FL are XML languages defined using XML schemas, while SM-SI is binary encoded.

Interactivity features that may be implemented by an SMR-enabled MPEG-4 player are specified in an amendment to the BIFS (BInary Format for Scene representation) specification (ISO/IEC 14496-11:2005 AMD5), which is used to describe the multimedia scene.

SM-XF: SYMBOLIC MUSIC EXTENSIBLE FORMAT

Symbolic music extensible format is an XML application for encoding main scores, single parts, as well as multilingual lyrics. In Figure 2, a simplified UML diagram of the SMR model is presented. At an abstract level, the main score consists of single parts, each single part consists of a sequence of measures, and each measure consists of parallel layers containing sequences of notes, rests, and other timed and untimed symbols that are organized horizontally on a staff. Each symbol (e.g., notes, rests, chords, etc.) can be associated with some qualifier symbols to represent some additional pieces of information on the symbol itself, such as expression symbols. A chord is modelled as a sequence of chord notes (one for each note head), and beamed notes are modelled as containers of musical figures. Additionally, there are other symbols, called horizontal symbols, spanning over multiple timed symbols (e.g., slurs, crescendo, diminuendo), that start at a specific musical figure and end at another musical figure. The horizontal symbols are contained

Figure 1. Example of structure and relationship among MPEG-SMR data and how a SMR enabled MPEG-4 player should use it

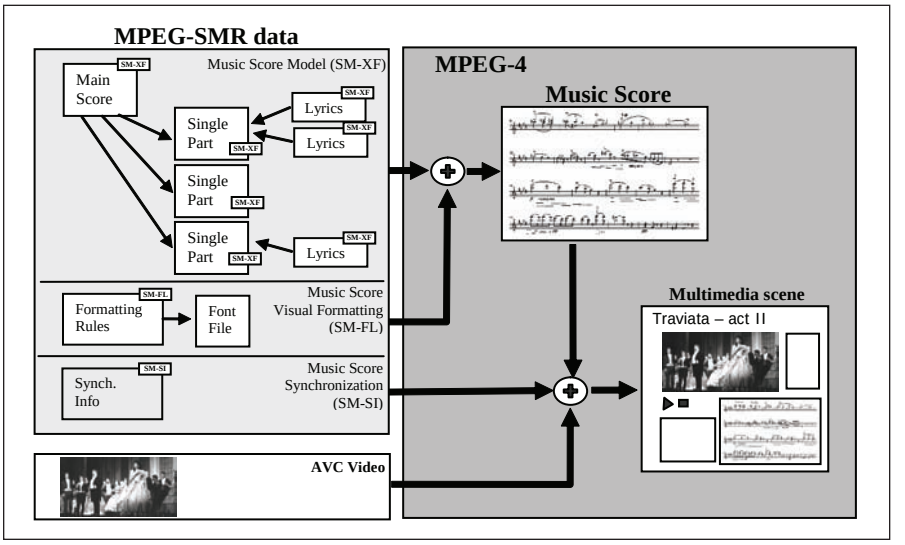

Figure 2. SMR abstract UML model

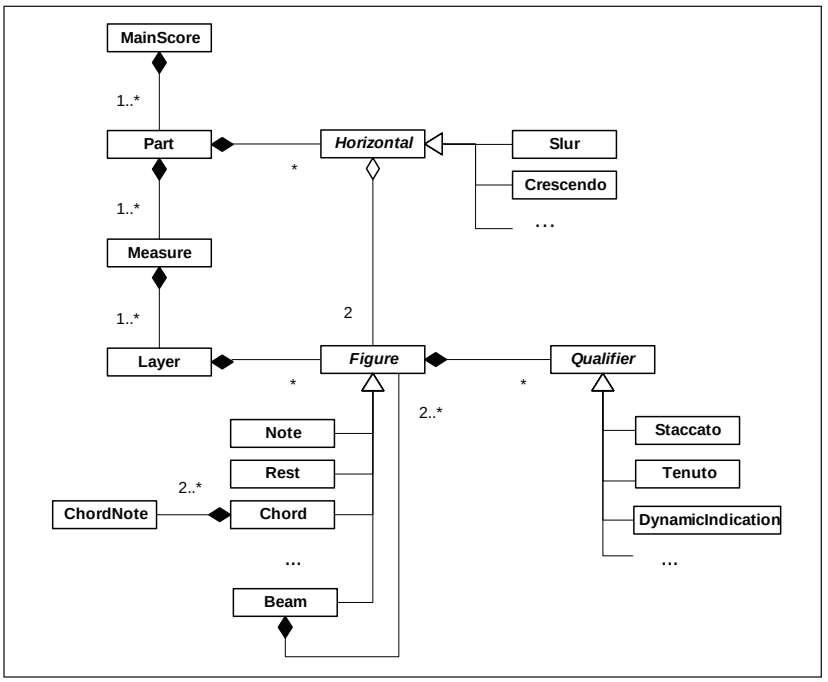


inside the single part and referred to the start/end figures/locations.

The MainScore representation is built from the Parts representation. Other formats use different representations for MainScore and Parts; thus, having a strong duplication (each part is provided twice, in the main score and in the single instrumental part). If the main score is built from parts, it reduces the size of the data (to be sent to the client) and supports a synchronized visualization of parts and main score (a modification made on a part in a main score view is reproduced mirror-like in the part shown in the single part view). In some cases, the main score and the parts are encoded differently, and some musical elements are present, specifically for the view (e.g., small guideline indications are used in the single parts) or different instruments are merged on a single staff in the main score representation. In such cases, the representation can be duplicated, and the main score and parts can be represented separately.

In SMR, a measure is represented as a container of musical figures. This is different from other formats such as CapXML (Capella, 2005), which does not group musical figures in measures and have the barline as another symbol among musical figures. However, the structural subdivision in measures enables subdivision of the content in chunks to be delivered to clients. In MPEG-4, all the media content (and subsequently also SMR) is delivered to clients in subdivided Access Units. The Decoder receives the Access Units one after another and it has to decode them, passing the decoded data to the renderer. In SMR, each Access Unit delivered to the terminals can contain one or more measures for the different parts. The whole score can be provided in one Access Unit or subdivided in many Access Units, thus enabling the device to start rendering the score without being restricted to wait for the whole score (consider the case of an opera containing hundreds or thousands of measures).

One of the main requirements in the language design consisted in each element (Part, Measure,

Layer, Note, Rest, Chord, ChordNote, …) being identified in a unique way to allow musical elements to be referred directly in the score.

This feature is used in:

- Horizontal symbols (e.g., slurs, dynamics) to indicate the start/end element of the symbol.
- Lyrics to indicate the note a syllable is connected to.
- Annotations to indicate to which musical symbols the annotation is related/associated to.

In all these occurrences, the information is stored outside the score itself. This feature allows a primary musical structure to associate additional information, such as annotations. Moreover, the musical element identification has to work, even if it does not have in memory the whole score (this is particularly useful for low-memory footprint devices), and the identifier has to be valid even after score manipulation (therefore, element position cannot be used as identifier). For these reasons, each element has been identified with a numeric ID that is unique in the parent element (Part in Main Score, Measure in Part, Layer in Measure, Figure in Layer, ChordNote in Chord). Hence, an element can be identified by using a sequence of IDs that specify the path to be followed in order to locate the element. The path is valid even if new measures/figures are added before the identified element. If each element is easily identified, this allows for things such as separate files for Lyrics or Annotations that can be applied without any modifications to the score.

Beams are modelled as containers of Figures inside Layers, thus not allowing beaming across measures. Hence, a kind of horizontal symbol used to beam notes from a start note to an end note has been introduced. In this case, the end note can be in another measure, to support beams across measures. This feature has been added only recently and both approaches can be used.

For instruments using more than one staff (like piano and organ), the staves are considered as belonging to the same score (other XML formats, like CapXML, encode each staff separately). The score has an attribute stating how many staves are used by the instrument, and each figure in a layer has an attribute indicating which staff the note/rest belongs to. Therefore, layers can go from one staff to another and can easily represent beaming across staff.

What follows is a set of selected examples on how the basic musical symbols are represented in SMR, starting from the bottom level (a note) and going up to a single part and a main score. The complete description of the XML language can be found in the ISO/IEC MPEG Specification (ISO/IEC 14496-23 FDIS).

In Figure 3, a brief explanation of the notation used to represent XML elements is reported.

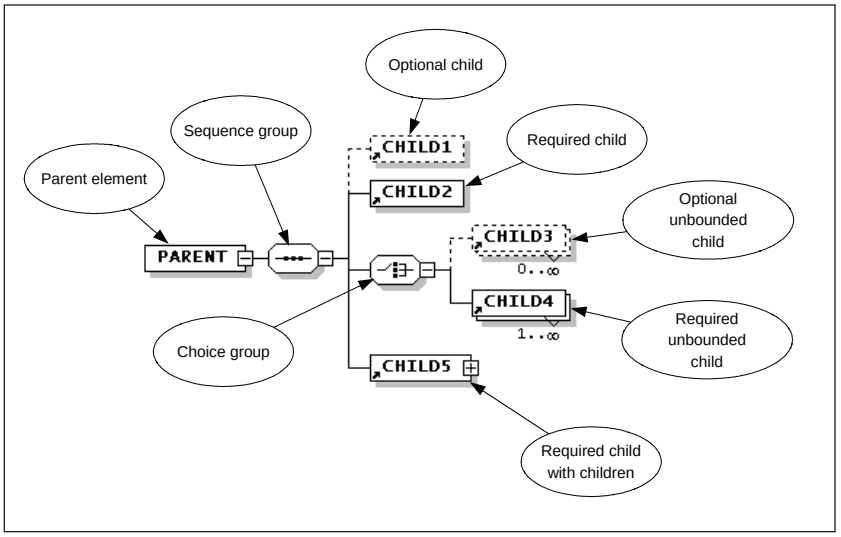
Note

The musical note is modelled in XML with the note element, as described in Figure 4 (attributes documentation is missing). A note element may contain:

- An optional pitch element with the note pitch indication.
- Accidental symbols (like sharp, flat, etc.).
- Augmentation information that modifies the note duration.
- A sequence of qualifier symbols like fermata, dynamic text, markers, and so forth.
- An optional user spacing with the distance with respect to the next figure.

If the pitch is missing, it can be deduced from the HEIGHT attribute containing the position of the note on the staff, from the accidental symbols, if any, and from the clef and key signature currently active. If both the height attribute and the pitch element exist, the height is used for visual rendering and the pitch information is used for

Figure 3. Notation used to represent XML element structure



audio rendering. In the event that the height attribute is not specified, the latter is deduced from the pitch and from the clef and key signature.

Some of the attributes of the note element are:

- The HEIGHT containing the position of the note on the staff (0 for the lowest staff line, 1 for the first space, 2 for the second staff line, etc.).
- The DURATION with the note duration (e.g., D1_8 for an eighth note).
- The ID, which identifies the note within the layer.
- The STEM to indicate the direction of the stem (up or down).
- The STAFF to indicate the staff where the note has to be positioned.

Figure 4 (on the right side) reports an example on how a note is represented in XML.

Rest

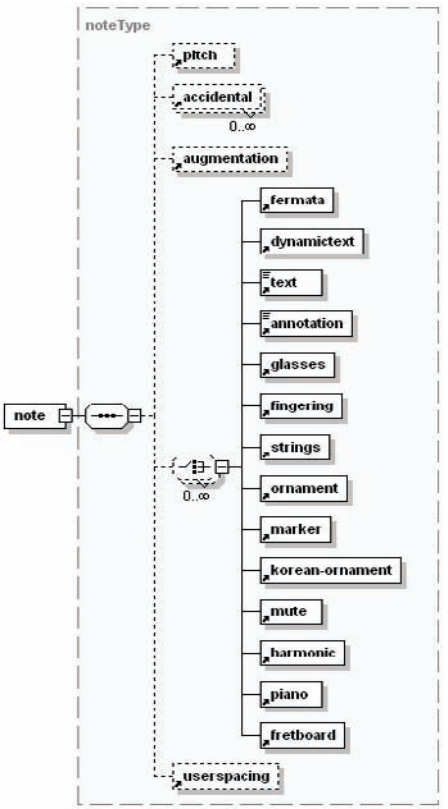
A rest symbol is represented in XML with the rest element, which may contain the augmentation information so as to change the rest duration. It may contain zero or more qualifier symbols, such as fermata, dynamic text, textual indication, annotation, pay attention symbol (glasses), piano symbol, and fretboard symbol. Moreover, it may contain the userspacing element expressing the distance from the next figure.

The rest element contains attributes such as the rest DURATION, the HEIGHT with the position of the rest on the staff, and the rest ID to identify the rest in the layer.

Chord

A chord is represented in XML with the chord element containing a sequence of chordnote elements, with the information related to each note head of the chord (accidentals, fingering, pitch, position on the staff, staff, …). The chord element contains the same elements of the note (fermata, dynamics, text, etc.), since they refer to the chord as a whole. The arpeggio element is specific for chords to indicate how to play the chord. Figure 6 depicts the XML element structure with an example of a chord.

Figure 4. XML model of a note (on the left) and an example (on the right)



```
<note ID="1" DURATION="D1_8" STEM="DOWN" HEIGHT="4">
   <pitch BASE="B" SHIFT="#" OCTAVE="4"/>
   <accidental TYPE="SHARP" ROUNDBRACKET="NO"/>
   <augmentation DOTS="1"/>
   <dynamictext DYNAMIC="F" UPDOWN="DOWN"/>
   <ornament TYPE="TURNBACK" UPDOWN="UP"/>
</note>
```

Figure 5. XML model of a rest (on the left) and an example (on the right)

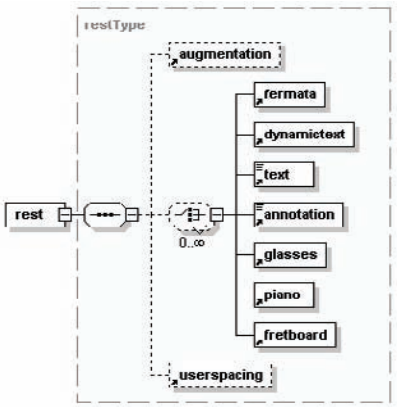


Figure 6. XML model of a chord (on the left) and an example (on the right)

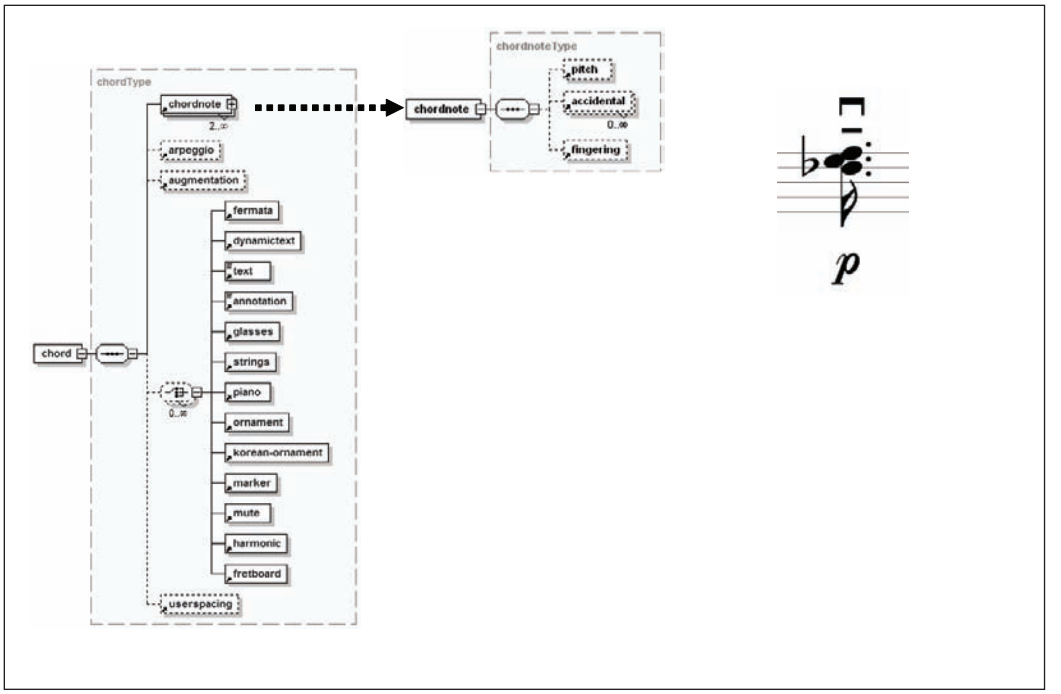

Beam

The beam is modelled as a container of notes, chords, rests, anchorages, and change clefs elements. The anchorage element represents a point in the score where other symbols (mainly horizontal symbols) can be logically attached. With this kind of model, a beam crossing the bar line cannot be represented; for this reason a specific horizontal symbol can be used (see later on). Therefore, a beam can be represented both as container and horizontal.

Measure

The measure represents the classical subdivision of a score; it is modelled with the measure element, which contains a sequence of layers containing the notes, rests, chords, beams, and so forth.

With some further details, the measure may contain:

- Justification information on how to position the notes/rests on the available space (e.g., linear or logarithmic with a tuning parameter).
- An optional label for the measure (e.g., rehearsal marks or "segno/coda" signs).
- An optional jump indication to indicate the successive measure to be executed (e.g., da capo al fine).
- A header with the clef and key signature for each staff.
- The time signature of the measure (e.g., 3/4).
- A beat scan indication.
- An optional metronome indication that applies starting from the measure until another metronome change.
- The different layers with the musical figures.
- The bar line to be used (e.g., single, double, refrain start/end, invisible).

 <timesignature TYPE="FRACTION" NUMERATOR="3" DENOMINATOR="4"/>
 <layer NUMBER="1">
  <note ID="2" DURATION="D1_4" STEM="DOWN" HEIGHT="4" STAFF="0"/>
  <note ID="3" DURATION="D1_4" STEM="DOWN" HEIGHT="4" STAFF="0"/>
  <note ID="4" DURATION="D1_4" STEM="DOWN" HEIGHT="4" STAFF="0"/>
 </layer>
 <layer NUMBER="2">
  <beam ID="13" STEMS="STAFF12">
   <note ID="1" DURATION="D1_8" HEIGHT="4" STAFF="1"/>
   <note ID="2" DURATION="D1_8" HEIGHT="4" STAFF="0"/>
  </beam>
  <beam ID="14" STEMS="UP">
   <note ID="3" DURATION="D1_8" HEIGHT="4" STAFF="1"/>
   <note ID="4" DURATION="D1_8" HEIGHT="4" STAFF="1"/>
  </beam>
  <beam ID="15" STEMS="STAFF12">
   <note ID="5" DURATION="D1_8" HEIGHT="4" STAFF="1"/>
   <note ID="6" DURATION="D1_8" HEIGHT="4" STAFF="0"/>
  </beam>
 </layer>
 <barline TYPE="SINGLE"/>
</measure>
```

Some of the attributes of the measure element are:

- An ID to identify the measure in the score.
- A progressive number;
- The number of staves to be used (1, 2 for piano, or 3 for organ).

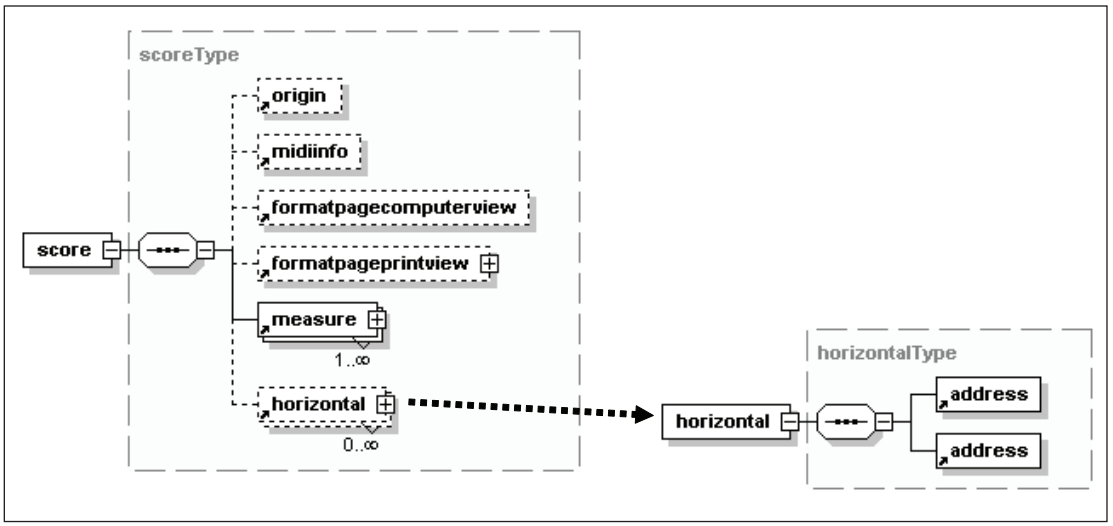
Figure 9 provides an example of a measure spanning on two staves. Please note that two layers are used, one for the notes on the upper staff and one for the notes on the lower staff, and in the second layer there are two beams with notes belonging to different staves.

Score and Horizontal Symbols

The score is modelled as a container of both a sequence of measures and horizontal symbols. Horizontal symbols are the ones spanning over the score from a start event/position up to an end event/position (e.g., slurs, crescendo/diminuendo). The start/end event/position may correspond to a musical figure, such as a note, rest, or chord, or to an anchorage point that represents an event between two musical figures. Since horizontal symbols are not stored within the measures but outside, what is needed is a way to logically identify the start/end element of the symbol. In order to refer to the start/end figure of the score, a set of identifiers is used in the address element:

- The ID of the measure where the start/end figure is.
- The number of the layer where the figure is.
- The ID of the beam/chord/note/rest within the layer containing the addressed figure.
- The optional ID of the note within the chord or the ID of the note/rest/chord within the beam.

Figure 10. The XML model of the score element



- The optional ID of the note within the chord in a beam.

Horizontal symbols are used for:

- Slurs
- Ties
- Tuplets (e.g., terzine)
- Octave change (8va, 8ba, 15ma, 15ba)
- Beaming across measures
- Crescendo/diminuendo
- Trill with a wavy line
- Bend
- A wavy line
- An arrow
- Refrain change
- Piano pedal indication

The score is represented in XML as illustrated in Figure 10. The score element can contain:

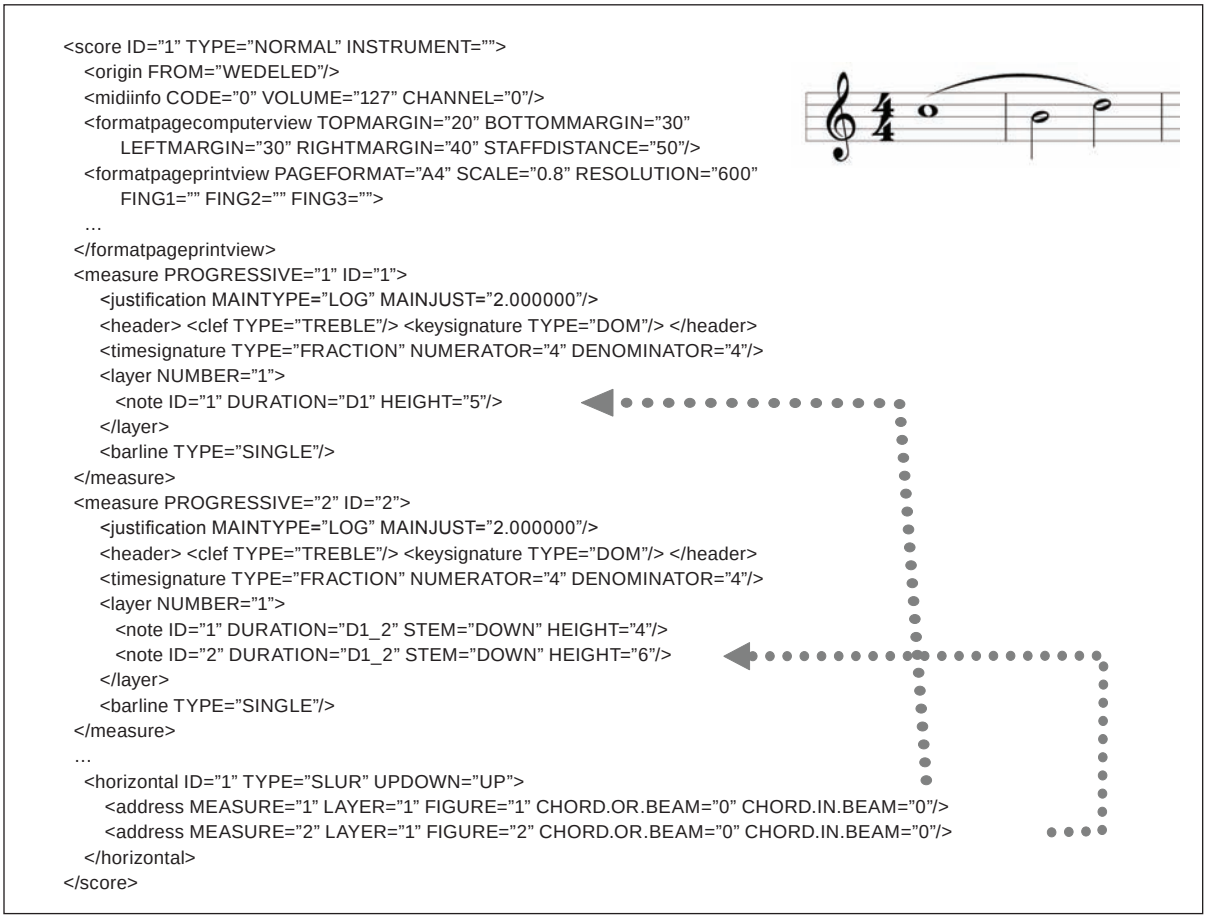
- Some optional origin information (e.g., the software tool used to produce the score).
- Some optional MIDI information on the instrument, volume, and channel to be used for MIDI execution.
- Some optional information on how to format the page for computer view and for print view (e.g., margins, distance between staves, number of systems per page).
- The sequence of measures building the score.
- The sequence of horizontal symbols, each one with two addresses identifying the start/end figure/event.

Attributes of the score element include:

- The score ID identifying the score
- The score type (e.g., normal, percussion, tablature)
- The instrument name
- The number of staves to be used (e.g., 1, 2 or 3)
- …

Figure 11 presents an example of a score with a slur connecting two notes.

Figure 11. An example of an MPEG-SMR score



Single-Part Score

The single part contains the musical information for one executor, and it is modelled with the SMXF_Part element. It contains the score element with the musical information and some general identification and classification information (as XML elements), some preferences for some specific decoder, and additional pieces of information for printing the score as a single part. The printpages element has textbox and imagebox elements, to be used when printing each page.

Main Score

The main score contains the musical information of the whole score and subsequently, it contains the information about all the single parts of the instruments playing the music piece.

Like the single part, the main score may contain identification and classification information and custom preferences for specific decoders. Moreover, the main score contains:

- References to the single parts making the main score (using the score IDs).
- Some general MIDI information (e.g., how to map to MIDI dynamic symbols).
- Some formatting information for the computer view and for print view (e.g., margins, distance between staves, number of systems per page).
- A sequence of brackets used to group visually different parts (e.g., string instruments).

Figure 12. XML model for the single part

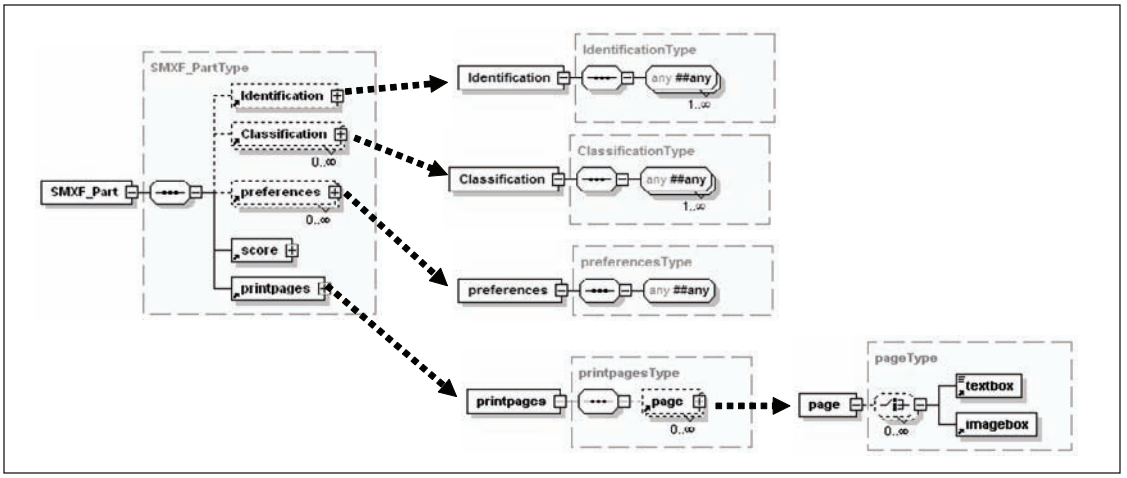


Figure 13. XML model of the main score

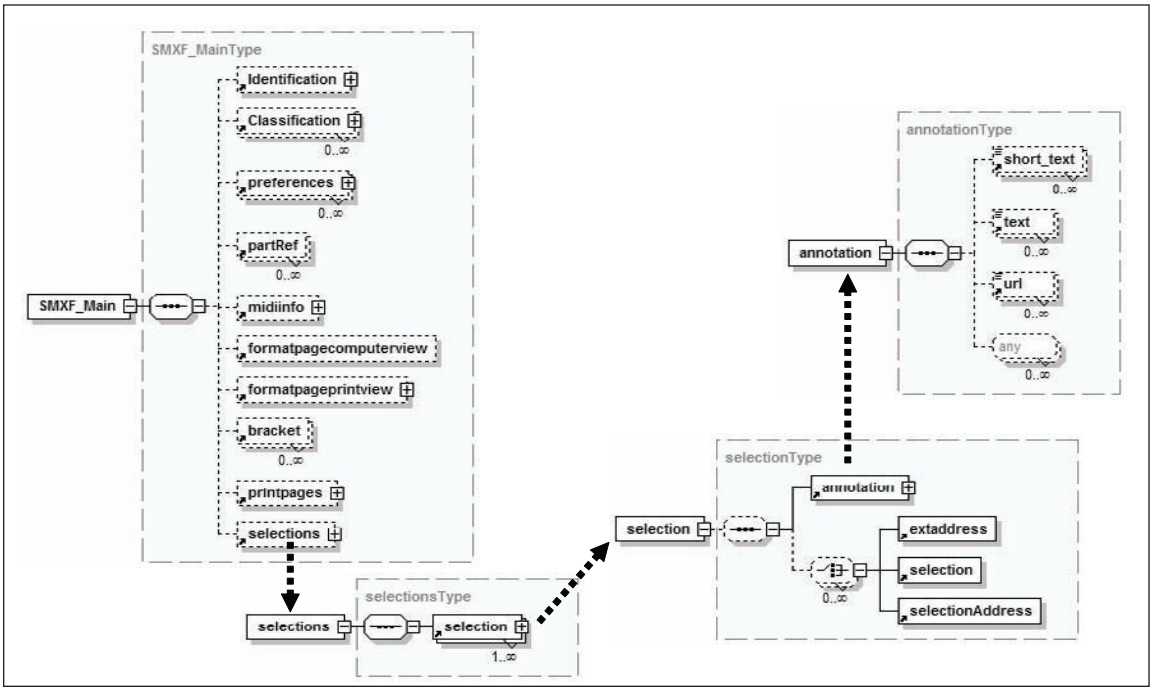

Figure 14. XML model for the lyrics

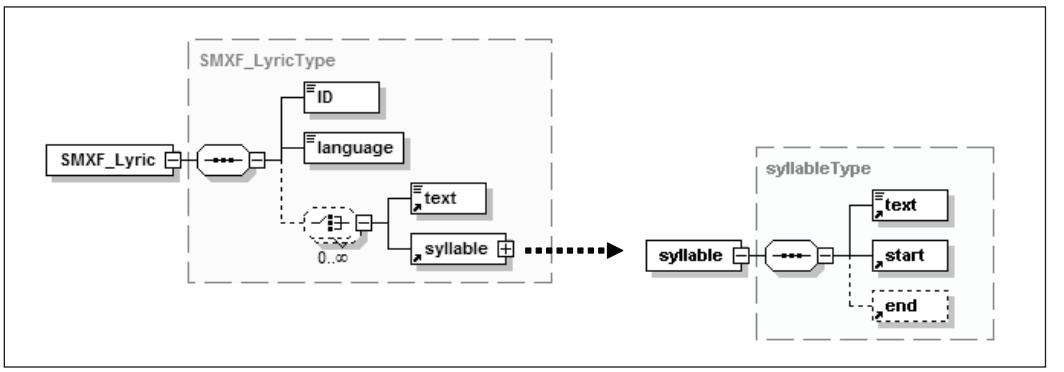

- Additional "graphical" elements (image and text boxes) for print view.
- An optional sequence of selections used to associate annotations (as text, URL, or any XML elements), with a subset of musical symbols of the different parts.

Selections are used to group together a subset of musical figures being included in the score, and to annotate them with textual descriptions (in different languages) or reference to a digital resource via URLs (e.g., an image contained in the MPEG-4 file), or with any customized XML content. A selection may be defined with extaddress elements that refer to the musical figures in the score (the extaddress contains the score ID that is not included in the address element of the horizontal symbols). Moreover, the selection can be built also by embedding other selections so as to form a hierarchical structure, or by referring to other selections using an ID (using the selectionAddress element).

Selections are useful in music education in order to mark specific passages or to give audio/visual performance indications.

Lyrics

The lyrics are modelled in a way similar to the horizontal symbols; the syllables of the lyrics are not spread over the notes in the score (like many other music notation formats) but are kept separate, and they refer to the notes they are associated with (using the same mechanisms of addresses, as it happens with the horizontal symbols). In this way, different lyrics (e.g., in different languages) can be plugged on a score without changing the score. Moreover, the original lyrics can be reconstructed as plain text, out of the lyrics model. This method to model lyrics is explained with further details in Bellini et al. (Bellini, Bruno, & Nesi, 2004).

The SMXF_Lyric element contains:

- An ID to identify the lyrics.
- The language used for the lyrics.
- A sequence of mixed text and syllable elements, where the text elements contain some accompanying text that should not appear in the score (e.g., some formatting text), and syllable elements containing information on the syllable.

The syllable element contains:

- The syllable text.
- A reference to the note the syllable is associated with (the start element).
- An optional end position in case of syllable prolongation like in melisma, where the same syllable is sung over more notes.
- An attribute with the row where the syllable has to be positioned, to be used in case of refrains.

In Figure 15, an example of lyrics is reported.

SM-FL: SMR FORMATTING LANGUAGE

The symbolic music formatting language (SM-FL) is defined to allow the description of the insertion point and the positioning of common music symbols (stem, ornaments, expression, etc.), as well as the definition of new symbols. It specifies a rule-based formatting language and engine that is used to describe sets of rules and conditions to be applied and interpreted whenever the position of symbols has to be estimated. The SM-FL rules define formatting actions; they assign specific values to specific parameters related to the visual rendering of the music symbols. For example, a rule is used to define the stem length of a note. The rule to be applied is identified on the basis of the conditions met in the music context of the symbol under evaluation. These conditions describe a music scenario. For example, a music scenario could consist of a note not belonging to a chord, that is, nonpolyphonic, and with a height set within a certain range. The verification of a music scenario defined by a conditional sentence leads to the application of a certain formatting rule to the symbol under evaluation.

SM-FL can be used to define rules to customize:

- Stem length and direction
- Beam slope and direction
- Automatic beaming rules
- Note head shape
- Stem start position
- Symbols' position and direction
- Symbols' positioning order (w.r.t. the note)
- Shape of any symbol

Figure 15. An example of MPEG-SMR SM-XF lyrics

```

  </syllable>
  <syllable LINE="1" SEP=" ">
        <text>the</text>
        <start MEASURE="10" LAYER="1" FIGURE="8"/>
  </syllable>
  …
</SMXF_Lyric>
```

SM-FL can be used to define new symbols associated with a note and rules to cope with their position in the score. The SM-FL is an XML language derived from the MILLA language used in WEDELMUSIC editor (Bellini et al., 2005). In Figure 16, the structure of an SMFL rule file is reported, it contains:

- A sequence of font-mapping definition elements where the shape of some classical symbols (clefs, alterations, etc.) can be redefined (those represented using fonts).
- A sequence of group definitions allowing to define new groups containing custom symbols.
- In any order: rule definition elements to set a particular aspect of the score (note head shape, stem direction, stem length, beam direction and slope, etc.) and rule application elements defining the condition for a specific rule's application.

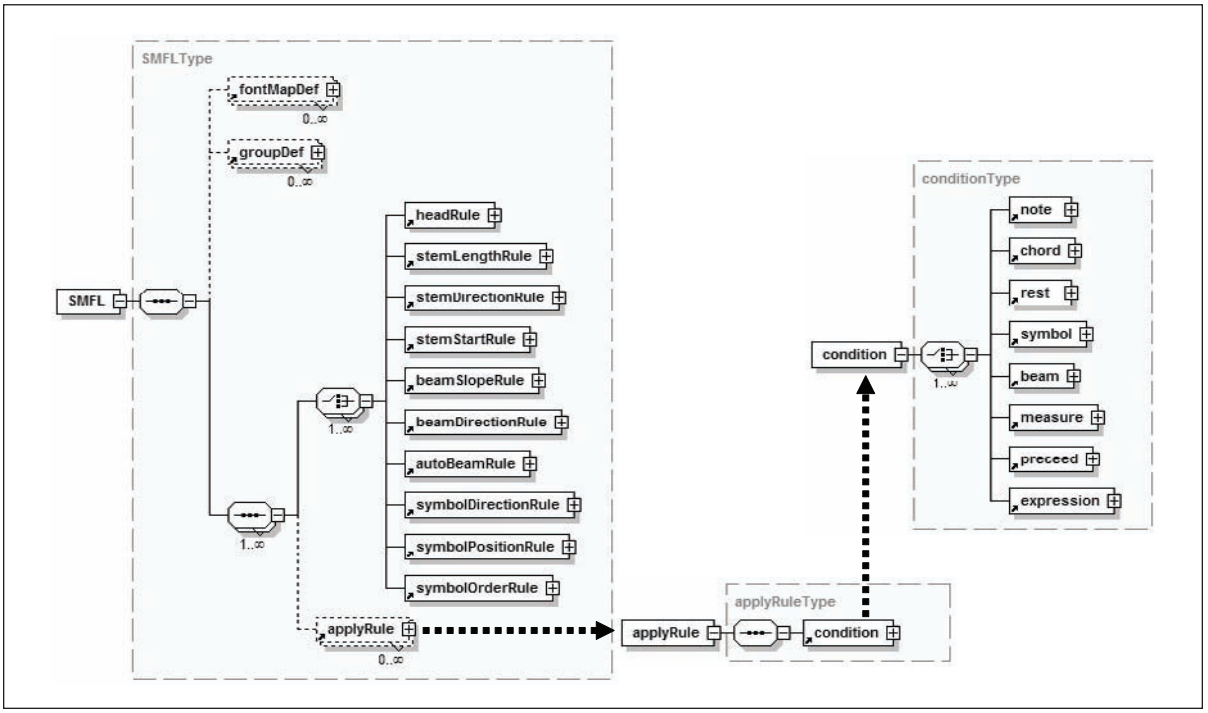
The only rule that is not conditional is the SymbolOrderRule, which is used to state the position of symbols with respect to the note head. In order to be applied, all the other rules need a condition to be satisfied.

For example, an insertion rule "StemUp," which sets the stem upward with respect to the note head, can be stated as:

```
<stemDirectionRule ruleId="StemUp">
        <stemUp/>
</stemDirectionRule>
```

A condition to activate this rule can be very simple. The condition could state that the rule "StemUp" is applied whenever the note is found below the middle line of the staff:

Figure 16. XML model for SM-FL



```
<applyRule rule=”StemUp”>
        <condition>
        <note>
                        <heightLT>0</heightLT>
        </note>
        <condition>
</stemDirectionRule>
```

A different condition may state that the rule “StemUp” is invoked if the note belongs to the upper voice for a measure having polyphony (In-MultivoiceUpper) as a feature. The upper voice is the one presenting the note with the highest pitch among those to be played at the same time:

```
<applyRule rule=”StemUp”>
    <condition>
        <note>
            <inMultivoiceUpper/>
        </note>
    <condition>
</applyRule>
```

Another case is when the note is in a single layer and is included in a chord:

```
<applyRule rule=”StemUp”>
  <condition>
    <note>
      <inSinglevoice/>
      <inChord/>
    </note>
    <expression>
      <lt>
        <minus><chord.upperd/><chord.lowerd/></minus>
        <value>0</value>
      </lt>
    </expression>
  <condition>
</applyRule>
```

Such conditions are met in the second measure of Figure 17. The notes belong to a chord (inChord), only one voice is present (inSinglevoice), and the difference between the highest and the lowest notes of the chord defines the “centre of gravity” of the chord, either above or below the middle line, that is (upperd-lowerd>0), where: upperd is the absolute value based on the distance between the highest note of the chord and the middle line of the staff, and lowerd is the absolute value based on the distance between the lowest note of the chord and the middle line of the staff.

Specific rules can be provided to set the stem length. The basic unit for stem length is the space defined as the distance between two staff lines. In this way, the standard length of the stem is 3.5 spaces, while it has to assume different values, depending on the note height. In Figure 18, the following rules and conditions have been used for some notes:

```
<stemLengthRule ruleId=”Stem3_5”>
    <length>3.5</length>
</stemLengthRule>
<stemLengthRule ruleId=”StemHeight”>
    <noteHeight/>
</stemLengthRule>

<applyRule rule=”Stem3_5”>
    <condition>
        <note>
            <heightGE>0</heightGE>
            <heightLE>7</heightLE>
            <stemDown/>
        </note>
    <condition>
</applyRule>
<applyRule rule=”StemHeight”>
    <condition>
        <note>
            <heightGE>8</heightGE>
            <stemDown/>
        </note>
    <condition>
</applyRule>
```

Figure 17. The stem of notes and chords in single layer and in polyphony

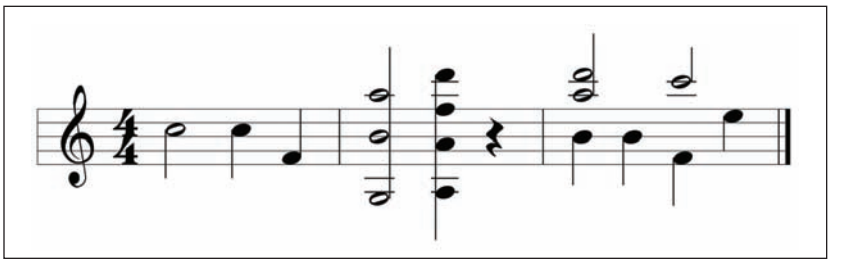


Figure 18. Example for stem length

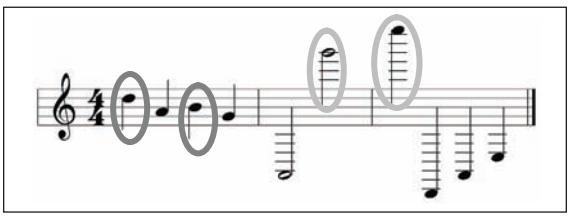

Figure 19. An example of order rule application

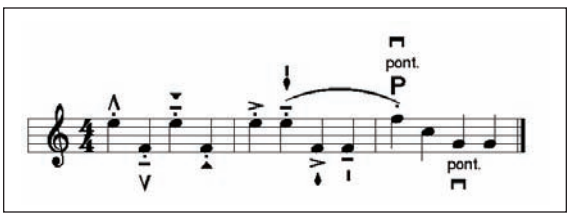


The first condition is verified for the first note of the first measure of Figure 18, while the second condition is true for the second note of the second measure and for the first of the third measure, which sets the use of a stem with a length equal to the note height divided by two.

Markers and other symbols may accompany the same note. In this case, the SymbolOrderRule defines the order of symbols' positioning.

To change the order rule is a procedure that can be used to change the order of symbols without modifying the symbolic description of music score. The order rule appears as a list of symbol identifiers shown in decreasing order of priority. For example:

```
<symbolOrderRule>
    <symbol>STAC</symbol>
    <symbol>TEN</symbol>
    <symbol>SLUR</symbol>
    <symbol>MARTF</symbol>
    <symbol>ACCE</symbol>
    <symbol>SFOR</symbol>
    <symbol>MART</symbol>
    <symbol>ARCO</symbol>
    <symbol>PUNTA</symbol>
    <symbol>TALLONE</symbol>
    <symbol>PONTICELLO</symbol>
    <symbol>TASTIERA</symbol>
    <symbol>ARCATASU</symbol>
    <symbol>ARCATAGIU</symbol>
    <symbol>CORDA</symbol>
    <symbol>PIZZICATO</symbol>
    ...
</symbolOrderRule>
```

Therefore, the staccato symbol (STAC, if any) is the symbol closest to the note head, the tenuto symbol (TEN) the second closest one, and so forth.

The SM-FL allows the definition of new symbols, which are considered as generic expression symbols related to a note. For these new symbols, rules can be defined. Since symbol rules are usually very similar, symbols are grouped and rules are defined for groups of symbols. However, specific rules can be defined as well.

A new symbol can be defined using the symbolDef element inside a groupDef element:

```
<groupDef name=”faces” font=”mysym.ttf”>
    <symbolDef name=”smile”>
        <code>33</code>
        <dimension>
                <toTop>20</toTop>
                <toBottom>20</toBottom>
                <toLeft>20</toLeft>
                <toRight>20</toRight>
                <dx>-20</dx>
                <dy>-20</dy>
            </dimension>
        </symbolDef>
        <symbolDef name=”sad”>
            <code>34</code>
            <dimension> … </dimension>
        </symbolDef>
        <symbolDef name=”star5”>
            <code>35</code>
            <dimension> … </dimension>
        </symbolDef>
</groupDef>
```

specifying:

- The name of the symbol (e.g., “smile”).
- The group it belongs to (e.g., “faces”).
- The name of the font where the symbol can be found (e.g., “mysym.ttf”).
- The code of the character representing symbol in the font file (e.g., code 36).
- The bounding box of the symbol in the dimension element (see Figure 20 for the meaning of the elements).

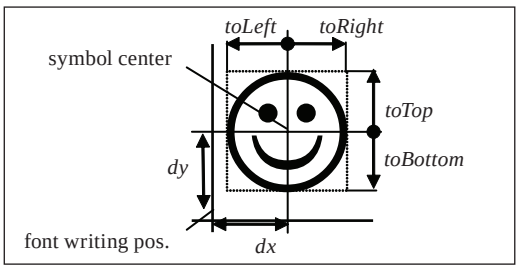
The rules for a group of symbols or for a specific symbol can be defined in the same way as for other symbols related to a note; for example, considering that the symbols in the group have to be positioned opposite to the stem in single voice and on the stem when in multivoice:

```
<symbolDirectionRule ruleId=”facesOppStem”>
        <group>faces</group>
        <oppositeToStem/>
</symbolDirectionRule>
<symbolDirectionRule ruleId=”facesOnStem”>
        <group>faces</group>
        <onStem/>
</symbolDirectionRule>

<applyRule rule=”facesOppStem”>
    <condition>
        <note>
            <inSingleVoice/>
        </note>
    </condition>
</applyRule>
<applyRule rule=”facesOnStem”>
        <condition>
            <note>
                <inMultivoice/>
            </note>
        </condition>
</applyRule>
```

As to the symbol position, other constraints can be specified: it has to be positioned on a space (not on a staff line) and outside the staff. This in both cases that the symbol is on the stem or opposite to stem:

Figure 20. meaning of dimension elements



```
<symbolPositionRule ruleId=”facesPos”>
    <group>faces</group>
    <onSpace/>
    <outsideStaff/>
    <dx>0</dx>
    <dy>0</dy>
</symbolPositionRule>

<applyRule rule=”facesPos”>
    <condition>
        <symbol>
            <oppositeToStem/>
        </symbol>
    </condition>
</applyRule>
<applyRule rule=”facesPos”>
    <condition>
        <symbol>
            <onStem/>
        </symbol>
    </condition>
</applyRule>
…
```

The symbol name (and not the group name) has to be used in the order rule to state the vertical relation of the symbol with other symbols, when it is placed on a note/chord:

```
<symbolOrderRule>
        <symbol>STAC</symbol>
        <symbol>TEN</symbol>
        <symbol>LEG</symbol>
        <symbol>MARTF</symbol>
…
        <symbol>PIZZICATO</symbol>
        <symbol>smile</symbol>
        <symbol>star5</symbol>
        <symbol>sad</symbol>
        <symbol>STRING</symbol>
…
</symbolOrderRule>
```

hence, the “smile” symbol has to be over the pizzicato and below the “star5” symbol.

SM-SI: SMR SYNCHRONIZATION INFORMATION

The SM-SI format contains information about the synchronization of the music score display with the whole multimedia scene where the music score is shown. For example, a multimedia scene may contain a video of an opera to be displayed synchronously with the music score of the same opera. Another possible case could be that the opera is a live event streamed over the network or through satellite and the music score has to be shown in synchronization with the live event.

The SM-SI is a binary format used inside MPEG-4 access units to provide to the SMR decoder the information needed to manage the synchronization. It has a different representation when it comes to synchronization with an off-line scene and with an online scene. In case of an off-line scene, the SM-SI data contain the sequence of measure numbers to be shown, with their corresponding duration expressed in milliseconds. Please note that the same measure can be repeated (with different durations) as it occurs with refrains. In the case of an online scene, the access unit coming from the transport layer (e.g., the network) with the SM-SI content contains the measure number to be displayed.

Figure 21. Notes with user defined symbols

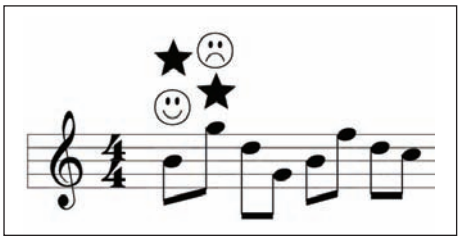


Figure 22. Off-line and online synchronisation using MPEG-SMR SM-SI

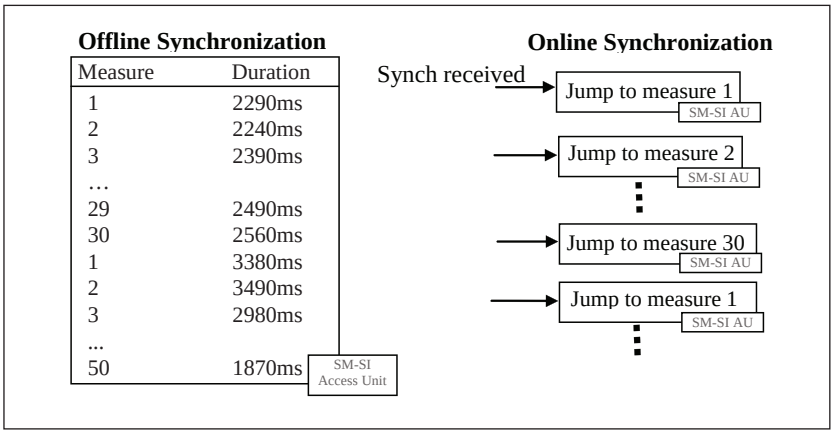

AUDIO GENERATION AND USER INTERACTION

It is possible to generate a MIDI representation of the music score by using the information contained in the score, namely, the metronome indication, the clef, and key signature currently active, while considering the dynamic indications included in the score. For transposed instruments, it is possible to indicate the transposition that should be used when generating the audio description. Moreover, each note can have both a visual indication of the note position on the staff and the note pitch. Whenever one of the two is missing, the other is calculated using the contextual information (clef and key signature). If the two elements are in contrast, the pitch is used for audio generation and the note position is used for rendering. Some parameters control the volume of dynamic indications (e.g., "f," "p," "mp," etc.), the MIDI instrument to be used for the score, the volume to be used for the instrument, and so forth.

The MIDI generated may be used as a score language by the structured audio engine, and together with the orchestra language (defining how to produce the audio), it can produce the synthetic audio.

The SMR format encoded as MPEG-4 files can be used by any application and not necessarily restricted to MPEG-4 conformant players only. For these applications, no specific requirements for user interaction are present. However, an MPEG-4 conformant player that supports BIFS scene representation (a binarization of a VRML extension) can use the MusicScore node (defined in ISO/IEC 14496-11 AMD 5) to display the music score, coming from an SMR stream, into the multimedia scene. The player can display the score synchronously with other media (natural audio, natural video, or 3-D models), and allows some interaction with the SMR content.

The MusicScore node manages the rendering and display of the score, and supports the following functionalities:

- Browse the score (jump to a label, jump to a measure, jump to a given time).
- Choose which parts/views to see (single parts, main score, main score with only some parts).
- Choose the lyrics to be displayed (in case of lyrics in different languages).
- Generate an event when a music element with an associated link is selected.
- Start/stop play the score in synch with the multimedia scene, highlighting the current playing position in the score.
- Transpose the score.

Figure 23. IM1 MPEG-4 Player showing a music score

- Perform some editing of the score (e.g., add textual annotation, add/remove notes, add/remove symbols, …).

Using the MusicScore node with the other nodes managing user interaction, like the TouchSensor node, the MPEG-4 Player can realize an interactive scene where the user can use and manipulate the SMR content. Figure 23 presents a snapshot of the IM1 MPEG-4 player (part of the MPEG-4 reference software) showing the MusicScore node.

CONCLUSION

This chapter presented the MPEG-SMR music representation formats that are under standardization in the ISO/IEC MPEG group. The SM-XF, SM-FL, and the SM-SI languages have been discussed in some details with a number of examples. SM-XF XML language is used to model the music notation as main score, single parts, and lyrics, while SM-FL is used to represent the formatting rules of SMR, and SM-SI binary format is used to transport synchronisation information with the multimedia scene. Other aspects of the integration with the other MPEG tools, like BIFS, are treated in another chapter of this book.

The presence of MPEG-SMR will enable and support the realisation of many new applications in the areas of education, entertainment, and cultural valorisation. Currently, most of these applications are not available on devices such as I-TV, mobiles, and so forth, and applications available on PC are not based on standard content formats. The absence of such a standard is constraining producers to create their own formats. This is one of the key challenges for the diffusion of music knowledge and for the market of music education.

It is hoped that SMR will become a way for multimedia frameworks, and particularly for MPEG to express a great potential in the domain of music enjoyment and fruition, and also in all its related usages and practices, including music education and musical performance.

Further information on MPEG SMR can be found via the MPEG ad-hoc group on SMR Web

page, http://www.interactivemusicnetwork.org/mpeg-ahg, where a large collection of documents reporting requirements, scenarios, examples, and links are available.

ACKNOWLEDGMENT

Thanks to Paolo Nesi and Giorgio Zoia for the help provided, and thanks to everybody who has participated in the discussions on the reflector of the MPEG ad-hoc group on SMR, all members of the MUSICNETWORK WG on Music Notation, and everyone who attended joined meetings of MPEG and MUSICNETWORK. Special thanks (in no particular order) to Jerome Barthelemy, Kia Ng, Tom White, James Ingram, Martin Ross, Eleanor Selfridge Field, Neil McKenzie, David Crombie, Hartmut Ring, Tillmann Weyde, Jacques Steyn, Steve Newcomb, Perry Roland, Matthew Dovey, and many, many others (apologies for not being able to mention everyone involved here).

Part of the development on SMR has been performed under the i-Maestro EC IST project cosupported by the European Commission under the 6th Framework Programme.

Chapter 8.9
Possibilities, Limitations, and the Future of Audiovisual Content Protection

Martin Schmucker
Fraunhofer Institute for Computer Graphics Research IGD, Darmstadt, Germany

ABSTRACT

This chapter explains the fundamental principles of audiovisual content protection. It explains the basic knowledge that is needed to understand the fundamentals of digital rights management (DRM) systems and their problems. Starting with a general introduction about copyright and content protection, available protection technologies are described and analyzed. The basic concepts of DRM solutions are explained and problems discussed. Potentials and practical limitations are analysed based on the digital music industry value chain. An outlook is given on solutions that are under development and that stronger consider the needs of the customers. In the conclusion, future solutions are discussed.

INTRODUCTION

I am about to put forward some major ideas; they will be heard and pondered. If not all of them please, surely a few will; in some sort, then, I shall have contributed to the progress of our age, and shall be content.

Marquis de Sade

Social and technical progress is one of the key issues of mankind. It is driven by the desire to disburden and to beautify life. Technical progress can be perceived in tangible goods like new devices, tools, and machines, while social progress cannot be perceived as easily. Both are based on a creative process resulting in new inventions and new ideas.

In law, the importance of this creative process is reflected by intellectual property (IP). "The term intellectual property reflects the idea that

this subject matter is the product of the mind or the intellect" as explained in "Intellectual property" (Wikipedia). Furthermore, it is explained, that IP rights (IPR) are more complex in the digital domain.

As the aim of IPR protection is to encourage new inventions, inventors, as well as authors, are granted (time-limited) exclusive rights for the exploitation of their works. Wikipedia identifies different intangible subject matters that are protected by IP laws:

- Copyright
- Patent
- Trademark
- Industrial design right
- Trade secret

As this chapter deals with digital (audiovisual) content, its focus is on copyright. The reader, however, should be aware that the described technologies are protected by patents and the mentioned products are protected by trademarks. This chapter is an updated summary of the technical report by Schmucker (2005c).

Copyright's main purpose is to prevent people from copying a person's original work. Copyright lasts for a specific duration.[1] After this well-defined period of time, the work enters public domain. The term copyright is generally equivalent to author's rights. Although certain organizations, like World Intellectual Property Organisation (WIPO), prefer the term author's rights, copyright is used within the area of DRM. The United States Copyright Office provides some general information on copyright and related issues (http://www.copyright.gov/).

Cohen (2002) describes how copyright changed due to the appearance of online work: Initially, copyright did not control access to, or private use of, an already purchased copy. Neither did copyright interfere with fair use derivatives. Nowadays, content owners claim the rights to control the access to, and the use of, content.

Music Copyright

Music copyright is a negative right, which means it gives the composer the right to restrict others from certain activities including copying music. Third parties who do not acknowledge these restrictions are liable for copyright infringements. Copyright automatically arises upon the creation of content without any formal registration process. Thus, copyright is distinct from other subsequent copyrights.

Music copyright includes different exclusive rights. As described in detail by Bell (2007), according to the U.S. copyright, a copyright owner has the right to:

- Reproduce copyrighted work
- Prepare derivative works
- Distribute copies
- Perform the work publicly
- Perform sound recordings of the work publicly

Further information on (music) copyright can be found, at:

- World Intellectual Property Organization (http://www.wipo.int/)
- Euro-Copyrights.org (http://www.euro-copyrights.org/)
- United States Copyright Office (http://www.copyright.gov/)
- Copyright for music librarians (http://www.lib.jmu.edu/org/mla/)
- "Copyright Issues for Music" at University of Buffalo Libraries
- 10 Big Myths about copyright explained by Templeton (2007)

Publishing Rights and Licensing

Copyright owners have the exclusive right to reproduce or make copies of their work. The copyright owner also has the exclusive right to

perform publicly a copyrighted work, directly or indirectly through means of communication or transmissions.

While these two rights (recording and public performance rights) were clearly separated before the digital distribution of content via the Internet, today this is not so clear anymore. Hence, service providers are forced to obtain multiple licenses from different parties. This process can be very difficult, as typically each right is connected with certain limitations, for example, geographical restrictions that can hardly be verified in the Internet. Rights can be negotiated either with the rights owner or with collection societies.

Legislation

International agreements that protect artistic and literary works aim to harmonize legal definitions and terms of protection. In the Berne convention, which was signed by more than 1,979 member states in 1979, such an international framework was determined. Yet, this framework has a degree of freedom to deviate from: As described by Cohen (2002), the copyright industries had secured an international commitment to additional legal protection for technological protection regimes in the 1996 WIPO Copyright Treaty, which leaves member states substantial flexibility in implementation.

The Digital Millennium Copyright Act of 1998 (DMCA, U.S.) forbids circumvention of access control technologies, and also the manufacture and distribution of circumvention devices. Hence, usage controls are protected indirectly. One side effect of the DMCA is shown by Craver et al. (Craver, Wu, Liu, Stubblefield, Swartzlander, Wallach, Dean & Felten, 2001) in the SDMI hack where the content industry tried to stop Felten distributing his research knowledge, cf. Felten (2001).

In Europe, the digital copyright directive was approved. This results in the classification of a range of devices that are to be prohibited. Yet, it leaves member states free to define what constitutes adequate legal protection against the act of circumvention. Member states may require preservation of exceptions (e.g., private noncommercial copying)

Furthermore, there are other legal frameworks, for example, the Uniform Computer Information Transactions Act (UCITA), which would validate consume "assent" to these restrictions, and legitimise the accompanying technological controls as part and parcel of the agreement.

Other potential areas of conflict are fair use and privacy. The possibilities of DRM are usage control. A qualification of the usage, however, is difficult. For example, devices and computers cannot distinguish between legal and illegal copying. Thus, a restrictive policy is enforced by DRM: No copying is allowed.

This led to interesting court decisions like in France, where the French court ruled that copy protection schemes have to be removed from DVDs, as described by Orlowski (2005). Similarly, the Deutsche Bibliothek (now German National Library) signed an agreement with the content industry that allows one to crack and to duplicate DRM-protected digital media. Here, DRM opposes the legal mandate of the German National Library.

The storage and exchange of personal information is sometimes considered critical as well. For example, a customer exchanges information with a third trusted party, which stores this information. This potentially infringes privacy of the customers, which is analysed, for example, by Grimm (2005).

Illegal File Sharing

Obviously, for very good reasons, content sharing is restricted. In the digital world, IP theft is not as obvious as theft in the physical world. In contrast to physical goods, digital content can be easily reproduced without quality loss. The copy is the original. Thus no other person experiences a lack of the digital content that was stolen.

Nevertheless, file sharing is against the copyright unless:

- The content is in public domain.
- The owner/creator gave permission to share it.
- The content is available under prosharing license (e.g., Creative Commons, http://creativecommons.org/).

As a result, the content industry successfully identified, and still identifies, users who illegally distribute digital content on the Internet via Web sites or via Peer-to-Peer (P2P) networks. Each user can be identified through the corresponding unique IP-address. This is required to receive information from the Internet. For permanent IP addresses, this is very easy (e.g., in the case of companies). In the case of dynamic IP-addresses (dial-in access), the Internet Service Providers (ISPs) temporarily store this information. The content industry was successful in identifying users by requesting user-related data from the ISPs.[2]

Nevertheless, this procedure is under strong discussion, and different verdicts exist in the different countries. Also the resulting lawsuits and their success are heavily discussed. Rudish (2005) states that "Eight of nine lawsuits filed last summer against Emory students accusing them of illegally sharing copyrighted music files have been dismissed, according to Senior Vice President and General Counsel Kent Alexander. The Recording Industry Association of America (RIAA) spokesperson Jenni Engebretsen said that one of the Emory cases has been settled, but she could not confirm the dismissal of the others."

Digital Rights Management

The term digital rights management (DRM) comprises technologies that allow the usage control of digital content. This goes beyond the possibilities copyright holders had before, thus DRM threatens user privileges. For example, fair use[3] or archiving of content is also restricted, as DRM systems restrict access to content. Unfortunately, there is no unique definition for DRM. Thus, when somebody faces the term DRM, the connotation associated with it must not be neglected.

In "Digital Rights Management and Libraries," a selection of different connotations is given:

- "Digital rights management technologies are aimed at increasing the kinds and/or scope of control that rights-holders can assert over their intellectual property assets." (as taken from *Electronic Frontier Foundation*, http://www.eff.org/)
- "DRM must be about the 'digital management of rights' not the "management of digital rights." (as described by the *W3C Workshop Report on DRM for the Web*, http://www.w3.org/2000/12/drm-ws/)
- "The purpose of DRM technology is to control access to, track and limit uses of digital works." (as seen by *The American Library Association*, http://www.ala.org/, itself)
- "DRM are the technologies, tools and processes that protect intellectual property during digital content commerce..." (as defined by the *Publishers' Requirements for DRM, W3C Workshop Report on DRM for the Web*, http://www.w3.org/2000/12/drm-ws/minutes/publishers.html)
- "DRM systems restrict the use of digital files in order to protect the interests of copyright holders." (as taken from *Electronic Privacy Information Center*, http://www.epic.org/)

Camp (2003) outlined the copyright system's legal, technological, and economic foundations with the aim to support the design of DRM systems. She identified several key functions[4], which should be considered in the requirements of a DRM system. Among these key functions identified by Camp are:

- Protection of the author's reputation
- Protection of the work's monetary value
- Archiving of content
- Ensuring of content integrity
- Providing surety through persistence[5]
- Facilitating personalization through filtering and annotation[6]

Although copyright defines under which circumstances copying is legal and when copying is illegal, copyright infringements are ubiquitous. Therefore several campaigns were launched addressing this topic. As discussed by Walter (2003), the MPAA launched an advertising campaign, copying is stealing, to sensitive public that IPR infringement by private people can be compared to stealing a CD from a record shop.

Similar threats to music can be identified even before the predigital age (before the 1980s), for example, shortly after the completion of the first pianolas in 1895 (http://www.pianola.org/), a Pianola copyright ruling was cited in 1899, according to Rhodes: "Boosey vs Whight (1899) involved copyright charges arising over the production of pianola rolls, in which the court found that the reproduction of the perforated pianola rolls did not infringe the English copyright act protecting sheets of music."

When analogue audio tapes and also video tapes emerged, potential threats caused by illegal copies were realized. As by Walter (2003), in the predigital age, several legal disputes are known where copyright owners claimed copyright infringement offences:

- Ames Records allowed subscribers to hire records from it for a small rental charge.
- Amstrad supplied tape-to-tape recording equipment.
- Sony's video recorders were used for illegal copying.

Interestingly, neither Ames nor Amstrad nor Sony was liable for copyright infringement. Before the introduction of the compact disk (CD) in 1982, music was typically sold on long playing (LP) vinyl records. The sales of LPs slowly declined with the introduction of the music cassette (MC), which allowed copying of music, cf. Lewis (2003). Content was, however, stored in an analogue representation. Copying this analogue content was not possible without loss of quality. Therefore a natural barrier existed limiting the amount of recopies. In addition to these natural barriers, copy prevention systems were developed. This natural barrier no longer exists in the digital world.

Nowadays, copying digital data is much easier, and commercially oriented pirates, as well as some consumers certainly do misuse this: Digital data can be copied without any loss of information, and distributed fast world wide via the Internet. Especially P2P file-sharing networks—the most popular one was probably Napster (http://www.napster.com/)—enable users to share content. After the US courts shut down the first version of Napster[7], rights holders still claim that Napster's descendants cost billions of dollars in revenues.

While the rights holders were quite successful against Napster, actions against other P2P-software suppliers like Grokster (http://www.grokster.com) and StreamCast (http://www.streamcastnetworks.com/) failed. These service suppliers cannot control the use of the technology by the end user, and the users' communication is entirely outside the control of the service suppliers. Today's descendants have a decentralized architecture and cannot be shutdown easily. As a consequence, rights holders now target consumers, ISPs, operators, and even founders of file sharing systems.

The content industry, especially the music and movie industry, nowadays sues P2P users who exchange content illegally. At the beginning of these activities, the P2P users reduced their illegal file exchange as outlined by Greek (2004). This resulted from the news that P2P users are sued for their IPR infringements. Additionally, the content industry started PR campaigns to raise

the users' awareness for the illegality of the file sharing of copyright protected content. Despite these activities, illegal P2P-usage seems to have increased again, and users have identified other ways of exchanging content, as discussed in Madden and Rainie (2005): "Beyond MP3 players, email and instant messaging, these alternative sources include music and movie Web sites, blogs and online review sites." Also, with portable storage devices, sharing content is very easy and convenient. Recent news related to P2P systems is available, for example, on People to People net (http://p2pnet.net/).

Although Verizon RIAA won a court order forcing an Internet Service Provider to disclose the identity of individual consumers who traded music files, technologies like Freenet[8] (http://freenet.sourceforge.net/) allow users to share any kind of content strongly reduced risk of being identified by rights holders. Obviously, P2P developments reacted on the content industries activities: While the first generation of P2P-file sharing networks has a centralised file list, the second generation is a purely distributed architecture. And the third generation addresses the anonymity of its users as outlined in "Peer-to-Peer" (Wikipedia).

Business aspects cannot be neglected when discussing and analysing protection technologies and illegal distribution. Unfortunately, there is no unique view on the influence of P2P exchange to the development of the traditional and the online market. On the one hand, each copied file is considered as a loss. On the other hand, some people consider downloaded content as an appetizer. Different reports and studies exist where common people have been interrogated about the influence of P2P networks. The results of the studies are contradicting, comparable to the results of studies trying to identify the reasons for the decrease in CD sales.

Besides these previously discussed methods and procedure, the technical endeavours of controlling the usage of content are summarized in the term digital rights management (DRM), and were first focused on security and encryption addressing the problem of unauthorized copying. But DRM evolved, and now it covers various issues including:

- The description of content
- The identification of content
- Trading and exchanging content
- Protection of content
- Monitoring/tracking of content distribution and its usage

As emphasised by Iannella (2001), DRM is the "digital management of rights" and not the "management of digital rights." Thus, it has become a very complex area addressing issues far beyond security and encryption.

The first section gives an overview of the current situation of copyright and content distribution. Section two introduces the available technologies for active and passive content protection. The following section, three, describes the application of individual techniques in DRM solutions. Their possibilities and limitations are discussed in the next section. New developments that try to embrace user requirements are described in the fifth section. An outlook discusses the future development of content protection of digital audiovisual content.

AVAILABLE TECHNOLOGY FOR AUDIOVISUAL CONTENT PROTECTION

Engineers like to solve problems. If there are no problems handily available, they will create their own problems.
Scott Adams

In this section, the basic technologies are described that are available for content protection. Some of these technologies are also relevant for other areas, like the content identification and the linkage of content and metadata.

Content Identification, Content Description, and Content Management

As already outlined before, content identification is an important aspect when content-related information has to be identified. For example, this is a central aspect of libraries and archives, where content-related metadata is managed.

Whenever data has to be accessed or retrieved, two issues are important:

- Content identification
- Content description

These issues are independent of DRM. But also DRM has to somehow identify content, as usage and rights information relate to specific pieces of content. In the following, a very brief overview on different standards for content identification and descriptions are given.

Content Identification

Content identification should be accomplished with an open standardized mechanism. Several open standards have been created for this purpose in the digital world. They allow identifying content or resources uniquely. Among the most commonly used are:

- International Standard Book Number (ISBN, cf. http://isbn-international.org/ or http://www.isbn.org/)
- International Standard Serial Number (ISSN, cf. http://www.issn.org)
- International Standard Music Number (ISMN, cf. "International Standard Music Number")
- Uniform Resource Identifier (URI, cf. "RFC1736", "RFC1737" and "RFC2396")
- Digital Object Identifier (DOI, cf. http://www.doi.org/)
- International Standard Text Code (ISTC, cf. "International Standard Text Code")

Content Description

Within a DRM system itself, the most significant content description is the licensing information. For completeness, general content description is summarized briefly.

According to Iannella (2001), content description should be based on the most appropriate metadata standard for each genre. Any overlap with other metadata systems might result in difficulties in the implementation due to redundant information.

Among the existing standards for content description are:

- Online Information Exchange (ONIX) as developed by EDItEUR (http://www.editeur.org/).
- IMS Learning Resource Metadata Information Model by IMS (http://www.imsproject.org/)
- Dublin Core Metadata Initiative (DCMI, http://dublincore.org/)
- Interoperability of data in eCommerce systems <indecs> (http://www.indecs.org/)
- "EBU metadata specifications" from the European Broadcasting Union
- Standard Media Exchange Format (SMEF), cf. "SMEF Data Model"
- MPEG-4 defines a stream management framework. This framework includes a rudimentary representation of metadata for the "description, identification and logical dependencies of the elementary streams" (http://www.chiariglione.org/mpeg/).
- MPEG-7 addresses the describing of and searching for content. "MPEG-7, formally named "*Multimedia Content Description Interface*," is a standard for describing the multimedia content data that supports some degree of interpretation of the information's

meaning, which can be passed onto, or accessed by, a device or a computer code." (http://www.chiariglione.org/mpeg/).

Rights Management and Rights Description Languages

As DRM is the digital management of rights, they have to be represented in a digital format to be digitally manageable. These digital representations must consider several aspects, as also described by Rosenblatt et al. (Rosenblatt, Trippe, & Mooney, 2002):

- **Content rights transactions:** Traditional business models.
- **Components of rights models:** Types of rights and their attributes.
- **Fundamental rights:** Render rights (print, view, play), transport rights (copy, move, loan), derivative work rights (extract, edit, embed).
- **Rights attributes:** (considerations, extends, types of users)

A general problem of DRM systems is the fact that they are not able to qualitatively distinguish between the different kinds of usage. For example, copying for personal purpose and copying for friends or even unknown persons is represented as the same action within a DRM system. This is what Rosenblatt et al. (2002) expressed as "they [digital rights models] don't do a great job of modeling the actual uses of content."

This is a potential starting point for further developments. The complexity of such an approach, however, might be beyond the relatively simple license (models), not only due to the potential dynamics of sociocultural aspects.

Today's licenses can have a strongly varying range of usage rights and conditions reflecting everything from simple to complex rights situations. Therefore, the language used for the description of rights should be able to model even very complex situations, which can appear easily when dealing with digital content (e.g., audiovisual material).

Rights Description Languages

The purpose of a digital license is to express who can do what with a specific content under certain conditions. For the digital management of rights, obviously, this license has to be expressed in a machine-readable way.

The extensible markup language (XML) is a de facto standard for the exchange and storage of data. Due to its flexibility, several rights description languages are based on XML. An overview of different XML-based rights description languages can be found in "XML and Digital Rights Management (DRM)." The currently most relevant ones are:

- Digital Property Rights Language (DPRL) and its successor eXtensible Rights Management Language (XRML, http://www.xrml.org/) are implemented by ContentGuard (http://www.contentguard.com/) and became an official standard within MPEG-21 (ISO/IEC 21000).
- Open Digital Rights Language (ODRL, http://www.odrl.net) was adopted by the Open Mobile Alliance (OMA).

Rights Processing

Expressing the rights in a machine-readable way is only the first step. Ideally the rights are processed automatically whenever content is created, derived, or exchange. This cannot be achieved yet as different terminology, especially when dealing with multinational content, and even different legal foundations complicate an automation process. Thus a rights ontology or thesaurus is inevitable.

Current Status of REL Standardisation

MPEG so far chose XrML as a basis for the MPEG Rights Expression Language (REL). Nevertheless, OMA was in favor of ODRL. This competition between XrML and OMA is very interesting, as XrML is patented and ODRL is royalty free. Nevertheless, "ContentGuard asserts that because its patents cover DRM implementations based on any rights language, even ODRL implementations should be subject to patent licensing from ContentGuard. The OMA tacitly disagreed with ContentGuard's assessment when it chose ODRL; the issue has yet to be tested, in the courts or otherwise" as pointed out by Rosenblatt (2004).

MPEG REL seems to be too complex and is hardly accepted by the market. Microsoft still prefers XrML. In March 2007, the first publicly known DRM patent licensing deal was done by ContentGuard. LG Electronics will apply XrML in it mobile handsets. A more recent overview of DRM related activities can be found at DRMWatch (http://www.drmwatch.com).

Encryption

Whenever data is transmitted over an insecure channel, which indeed is the Internet, the only possible protection mechanism to guarantee confidentiality is encryption.[9] The methods used for encryption can be attacked. These attacks are not limited to the encryption algorithm itself. Attacks are also possible against keys or protocols. In this section, we will address some general aspects of encryption to allow a basic understanding of distribution systems and related requirements. Detailed information on encryption and cryptography was given, for example, by Menezes et al. (Memezes, Oorschot, & van, Vanstone, 1996) or Schneier (1996).

Cryptography

Cryptography is the art of encryption and is several thousand years old. Encryption transforms the content by using an encryption algorithm or a cipher. Retransformation of the original message (or plain text) from the encrypted form (or cipher text) is known as decryption. To prevent others from reading the cipher text, the method could kept secret or the algorithm uses a secret to determine the transformation. Kerkhoff (1883) already formulated in 1883 that security by obscurity is not possible: Keeping the encryption method secret does not increase the security of the method. The security of an algorithm therefore must not be based on its secrecy but on the usage of a key.

Different methods exist:

- Symmetric encryption methods
- Asymmetric encryption methods

Symmetric Encryption Methods

Whenever data is exchanged, communication partners agree on a common key for the encryption of the data, as shown in Figure 1. As the same key is used for encryption and decryption by symmetric encryption methods, everybody who has access to the key can decrypt encrypted data.

Symmetric encryption algorithms include:

- **Substitution algorithm:** By using a table every character is replaced by another one.
- **Vignere method:** A password determines the mapping.

One severe attack is the knowledge of an instance of encrypted and the decrypted data, that allows the calculation of the mapping and therefore, the decryption of other encrypted messages. But also statistical attacks can be applied. Of course the system security depends on the

Figure 1. Symmetric encryption methods use the same key for encryption and decryption. The key determines the transformation for the plain text to the cipher text. Thus, everybody who has knowledge about the secret key can decrypt the cipher texts, which have been encrypted with this key.

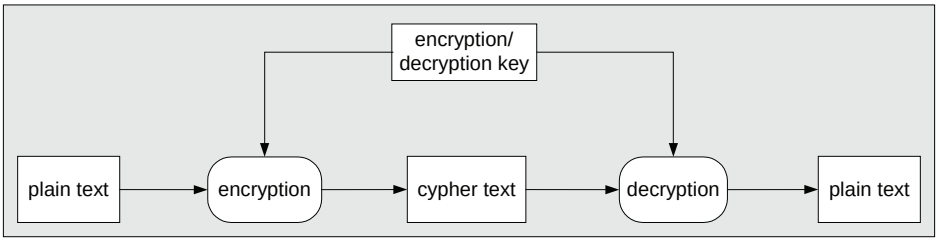

Figure 2. In contrast to the symmetric encryption algorithm, the asymmetric encryption methods use different keys for encryption and decryption. The public key can be accessed by everybody interested in encrypting a message for a certain receiver. The private key is kept secret.

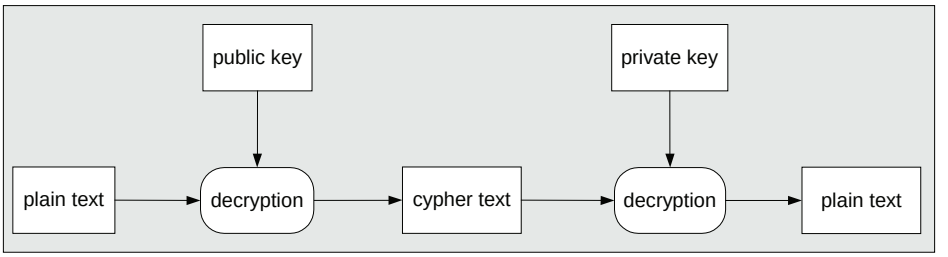

length of the password or key. If the key has the same length as the message maximum, security is achieved. In this case the key is also called a one-time pad.

There are two main types of symmetric encryption algorithms that differ in the size of the data the cipher works on:[10]

- Block ciphers process a number of bits simultaneously, for example DES, 3DES, IDEA, AES, Blowfish, Twofish, and RC6.
- Stream ciphers process a single bit at a time, for example, RC4.

Asymmetric Encryption Methods

The general problem of the symmetric schemes is the exchange of secret keys. As the secret key has to remain secret, the transmission of keys in plain text is not possible. This problem is addressed by public-key or asymmetric encryption methods.

Asymmetric encryption methods use two keys:

1. The public key is for the encryption of data. This key can be distributed freely.
2. The private key is used for the decryption of the data.

Thus, no keys have to be exchanged. One can even think of a "telephone book" that publishes the e-mail addresses and the corresponding public keys. Yet, public key encryption is computationally expensive.

The existing solutions for the asymmetric methods are based on the computation of mathematical calculations that are extremely difficult for very large numbers, like done, for example, in:

- ElGamal
- RSA
- Elliptic Curve Ciphers (ECC) probably will replace RSA in the future

Key Length

The comparison of different ciphers based on their key lengths is meaning less: The security is influenced by the design of the ciphers. One example is public key algorithms' key length: They require much longer key lengths than symmetric algorithms.

Recommendations on the key lengths are given by different national organizations. A collection can be found at http://www.keylength.com/. These recommendations consider that advance of cryptoanalysis.

Cryptoanalysis

Cryptoanalysis deals with the analysis of cryptographic methods. For example, the "brute force" attack is a straight forward attack that calculates and verifies all possible keys. Of course this can be very time-consuming, but for certain encryption algorithms, hardware was developed to speed up this task, and even distributed calculations that use a huge amount of computers connected via the Internet are performed. A method can be considered as secure when the most effective attack is the "brute force" attack. However, cryptoanalysis is not limited to the decryption of the secret message: collecting any kind of information, which provides more information about the secret message, represents an attack.

Dangers and Attacks

The security of all asymmetric encryption methods depends on the computational complexity of the corresponding mathematical problems. A tricky calculation or quantum computers might endanger the security of all asymmetric encryption methods in the future.

Besides this potential risk, attackers can exploit other leaks like the previously mentioned randomness of a PRN generator. Further possible leaks are cryptographic protocols, chosen keys, short pass phrases, and so forth. Even more sophisticated attacks are applicable, like the ones based on the power consumption or the time delay of cryptographic coprocessors.

One-Way Encryption

Encryption with one-way algorithms[11] cannot be reversed. Typical applications are scenarios, where the plain text must not be recovered, and include the storage of passwords. One of those one-way hash algorithms is the secure hashing algorithm (SHA) that creates a 160-bit hash value. As these one-way encryption functions typically base their calculations on a password, they can be used to sign data with a digital signature.

Depending on the application, for example, like for authentication/verification of digital content, the security of one-way encryption is very significant. Recent attacks on MD5, as shown by Wang et al. (Wang, Feng, Lai, & Yu, 2004) or on SHA-1 MD5, as outlined by Wang et al. (Wang, Yin, & Yu, 2005), show that collisions are possible, and that MD5 and SHA-1 can no longer be considered secure.

Applications in DRM Systems

Encryption technologies are primarily used to secure the communication between different parties, and the storage at the parties' storage media. While this is reasonable in business environments, concerns have to be raised with respect to the encrypted storage of content at the consumers' side. As consumers access the encrypted data, an unencrypted version must be temporarily available in the memory of the computer. As a matter of fact, consumers that are capable of handling debugging software are also able to access this decrypted content as long

as trusted hardware solutions are not available. This is discussed next.

Besides the secure communication and storage of content encryption, technology is used for further applications:

- Verifying content based on digests.
- Verifying identities based on certificates.
- Verifying identities and content based on signatures.

Watermarking

Besides the active protection technologies, like the previously described encryption and cryptography, passive protection technologies provide further possibilities in protecting content. For example, passive protection technologies address the identification of content or the identification of content owners. Thus, they do not prevent copying, per-se. These mechanisms, nevertheless, can be used for the detection of IPR infringements, as shown in the different movie piracy cases where several Oscar screeners—among them were *The Last Samurai*, *Shattered Glass*, and *In America*—were illegally distributed on the Internet in illegal file-sharing networks (cf. "Arrest In 'Screener' Upload Case," "FBI Arrests Internet Movie Pirate," and "Man nabbed for uploading Oscar 'screener'").

This section describes digital watermarking techniques, which allow embedding arbitrary information directly into the any multimedia content imperceptibly. The embedded information depends on the application. For the protection of intellectual property, typically, information about the rights holder is embedded. Information about the content itself, or a link to corresponding metadata, can be embedded, which supports the identification of content. Other scenarios embed information relevant for authentication[12] or even information related to marketing and PR.[13] In some applications, for example, for transaction tracing, as it was in the case of the Oscar screeners, the embedded information might consist of a customer identifier.

On the one hand, perceptible watermarking techniques influence the quality of the multimedia content. On the other hand, a successful removal can be easily verified by an attacker. Therefore we will limit this discussion on imperceptible watermarking techniques.[14]

In contrast to steganography, where the most important requirement is that the communication remains undiscovered, in digital watermarking, the information, if a message was embedded or not, can be publicly available. This knowledge leads to increased requirements on the robustness and the security of the communication respective of the embedded message. Thus, a good watermarking system maximizes robustness for a constraint-perceived quality degradation.

Characteristics and Requirements

The general principle of watermarking methods can be compared with the symmetrical encryption.[15] Both methods require the same key for encoding and decoding the information. A watermarking system consists of two subsystems: the watermark writer (encoder) and the watermark reader (decoder).

The embedding process is shown in Figure. Watermarking technologies' most important characteristic is the active embedding of a watermark message (e.g., an identifier) in the content. Thus, the content is modified (imperceptibly). This message is read during the retrieval process, as shown in Figure 4. This has severe implications to the protection scenario as in some cases, unmarked content that is already distributed has to be considered carefully.

The retrieval processes (as shown in Figure 4) of existing methods differ in the detection itself as well as in the number of input parameters. Blind[16] detection schemes require only the marked content and the detection key for the detection. In contrast to the blind detection schemes, the

Figure 3. During the watermarking embedding process the watermarking message is interwoven with the original content

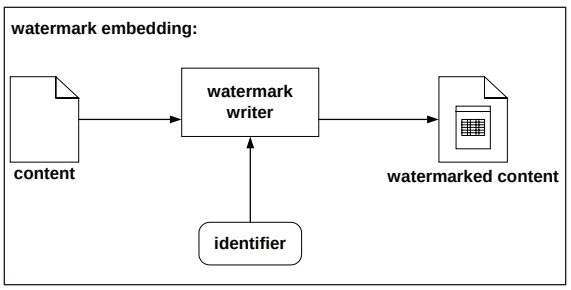

Figure 4. During the retrieval process the embedded watermark message is restored

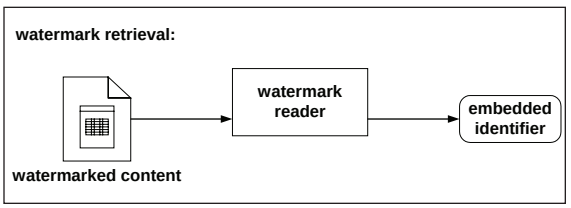


nonblind[17] methods require, in addition to the previous parameters, the original and sometimes the embedded watermark message. Semiblind methods require, in addition to the blind detection schemes, the watermark message as a retrieval parameter.

Nonblind methods are practically relevant only for a very limited number of application scenarios due to the necessary input of the original. In the typical application scenarios, like broadcast monitoring or the automatic identification of the copyright owner, the original is either not known or not immediately accessible.

General requirements on watermarking techniques are:

- The quality can be considered as the most important criteria. In general, the embedding of a message into the content should not affect the perceived quality of the content (the information carrier). As perceived quality always depends on the media type, watermarking techniques have to be developed or adapted to individual media types (e.g., choosing a suitable perceptual model to minimize distortions).[18]
- The robustness is defined by the types and numbers of operations (and their parameters) applied to the watermarked content, which can be survived by the watermark message. From a watermark developer's and user's view, these processing operations are called attacks. Depending on the intention of the operations, they can be distinguished between intentional and unintentional attacks. Although an attacker has numerous attack operations available, their combination and their parameters cannot be chosen arbitrarily, as the result also has to fulfill a certain quality requirement as well. The operations a watermarking scheme should be robust against are defined by the individual application scenario. For the identification of content and protection of IPR robustness can be considered as the second most important criteria.
- The capacity is the amount of information, which can be embedded in the content. It is the third most important criteria. Due to the mutual dependencies between quality, robustness, and capacity, a certain quality level is defined (according to the application scenario), and the robustness is chosen dependent on the deserved quality. Capacity is finally defined by quality and robustness.
- The complexity of an algorithm is important for certain application scenarios where real-time embedding or detection is important.
- The security of a watermarking scheme does not only depend on the robustness, but also on other issues like the used key and the message embedding method. Also, its implementation and integration into the overall system cannot be neglected.

General information on watermarking techniques was collected by Katzenbeisser and Petitcolas (2000). Cox et al. (Cox, Miller, & Bloom, 2002) provide a detailed technical inside on watermarking schemes for images. An application-oriented introduction and detailed information about requirements and application scenarios is given by Arnold et al. (Arnold, Schmucker, & Wolthusen, 2003).

Limitations

Watermarking schemes are advantageous as they allow the embedding of arbitrary information directly into content. This embedded information can survive processing and media conversion. In the sense that compression techniques remove imperceptible information, they can be regarded as competitors. Thus, the effect of future emerging compression techniques on the embedded information is unclear.

In IPR protection scenarios, watermarking techniques certainly have some limitations. For example, the robustness of watermarking schemes might not be sufficient, and an attacker might be able to remove, or maybe copy, a watermark message. Nevertheless, an attacker cannot be 100% secure about the success of his attack.

Available objective tests and performance analysis of existing watermarking techniques address a limited scope. These benchmarking suites like Stirmark by Peticolas (2006) or Certimark (http://www.certimark.org) do not fully consider practical requirements. Here, standardized application scenarios defining requirements would be advantageous. Another limitation is the missing standardization of the embedded information.

Applications in DRM systems

Although watermarking techniques must be developed for individual media types, a broad range of watermarking algorithms are available for various media types including audio, images, video, geometry data, text, music scores, and so forth. Several requirements can be addressed by integrating watermarking techniques into DRM solutions, as also described by Rosenblatt (2002):

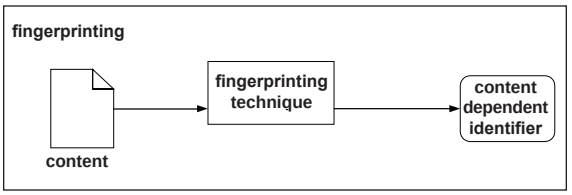
- Source identification can be achieved by imperceptible watermarking techniques, which do not affect the perceived quality. The information embedded links to the content owner or to a rights owner.
- Tracking and tracing by embedding so-called transaction watermarks, which is information about people involved in transactions, might allow the detection of leaks within the distribution chain.
- Metadata labelling stores a link to a database containing metadata information.

From a security point of view, applications involving encrypted watermarks and encrypted files with watermarks should be considered critically if they are used for access control in end-user devices. Yet, Rosenblatt et al. (2002) concludes "a scheme that incorporated both encryption and watermarking is not foolproof, but (all else being equal) it's the best DRM scheme available."

Fingerprinting or Perceptual Hashing

In contrast to watermarking techniques, which modify content, fingerprinting, or perceptual hashing techniques can identify content and fragments thereof without prior modifications. Thus, they have an inherent advantage if used in application scenarios where content cannot be modified, for example, as already distributed or due to workflow limitations. In this section, we explain shortly the idea and application of fingerprinting technologies.

Figure 5. The fingerprinting method calculates the content dependent identifier directly from the original content. Thus the content has not to be modified.



General Principle

Fingerprinting techniques calculate a content-dependent identifier, as shown in Figure 5. This content-dependent fingerprint can be compared with a human fingerprint: It is a unique identifier for renderings, and the original content cannot be created out of this identifier. Thus these techniques are also related to the cryptographic one-way functions. The significant difference to cryptographic hash functions is that cryptographic hash functions map similar input values not to similar hash values. For fingerprinting techniques, the opposite requirement must hold. Therefore, they are also called perceptual or soft hashing functions.[19] Perceptual hash reflects the fact that perceptual similar content should result in a similar hash value. Fingerprinting techniques are methods for content based identification (CBID).

Due to this property, fingerprinting solutions are very suitable for identification applications, like automatic play list generation or broadcast monitoring, as described by Allamanche et al. (Allamanche, Herre, Hellmuth, Froba, & Cremer, 2001). Further potential applications include the tracking of content flow or even restricting the content flow (e.g., in corporate networks). Due to these characteristics, fingerprinting techniques have attracted increased attention recently. A very good overview on the basis of audio fingerprinting is given by Cano et al. (Cano, Baltle, Kalker, & Haitsma, 2002).

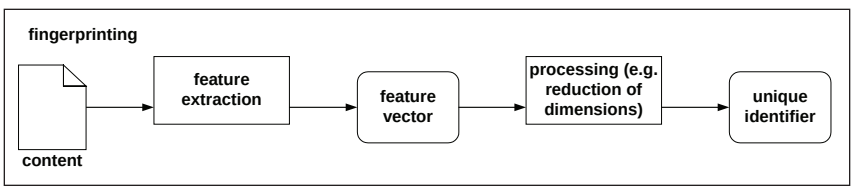
Characteristics and Requirements

Fingerprinting techniques are related to content-based retrieval (CBR). CBR methods create a content-dependent signature directly from the content. This signature is also compared to pre-calculated and stored content signatures.

Figure 6 shows the principle steps necessary for the calculation of a unique identifier. First, features are extracted from the content. These extracted features typically have very high dimensions and are processed further, resulting in unique identifiers.

The feature extraction process itself might extract features that are directly perceived by humans, like the frequency characteristics (melody) in the case of audio signals. On the contrary, features that do not directly depend on the human perceptions can also be used, as long as they allow the automatic discrimination of content. A typical example is the sign of the difference between neighboring (frequency) energy bands, as proposed by Haitsma et al. (Haitsma, van der Veen, Kalker, & Brueker, 2000).

Figure 6. For calculating a unique identifier, (perceptually) relevant features are extracted. These features are processed to reduce their dimensionality.



Without a following processing step, the dimensionality of the feature vector would be very high. Therefore, the dimensionality is reduced by removing redundant information. During this processing step, further improvements, for example, error resilience, can be achieved. Although the aim is to receive a compact digest, the discriminability of this digest still has to be sufficient.

In addition to the feature vector, a suitable distance measure is required. This is also related to CBR methods, where it defines similarity. Typical distance measures are the Euclidean or related distance measures or distance measures based on correlation.

The retrieval architecture strongly influences the complexity and the scalability of the fingerprinting technique. Efficient spatial access structures have been developed like indices, or application-oriented approach like the ones used for DNA information processing. In the retrieval architecture, a final hypothesis test calculates the probability of the correct identification of the content.

In the case of content identification, a good performance in discriminating a huge amount of data and corresponding fingerprints is crucial. Similarly to watermarking techniques, requirements can be identified:

- The robustness can be defined by the types and numbers of operations and their parameters applied the content, which does not effect the retrieval of the content. Typical operations depend on the application scenario where the fingerprinting method will be integrated in. For example, when a system should be able to recover the song from a radio transmission that is recorded via a mobile phone, the fingerprinting system should be capable of the reduced frequency band available due to the mobile phone. Also small audio extracts somewhere within the song must not result in misidentification, as humans will rather realize in the middle or at the end of the song that is worth being remembered or purchased. Finally, a noisy background will probably be the general recording place, for example, in a car, bar, club, or café.
- The discriminability determines the capability of how many content items can be identified.
- The scalability is an important practical criterion. Today, millions of different types of audio content exist. Some of them are even available in different editions, for example, studio or live performance recordings. In this case, a system should be capable of handling all available works in a reasonable amount of time, where "reasonable" is again defined by the application scenario.
- The complexity of an algorithm is important for certain application scenarios where real-time identification is important.

In contrast to watermarking applications, so far security is hardly considered. This might be caused due to the fact that perceptual hashing techniques, so far, are mainly applied in CBID scenarios, where security can be neglected. In authentication scenarios, however, security is crucial and requirements are different.

Limitations and Comparison to Watermarking

Different limitations have to be considered when a fingerprinting technology is deployed. As already mentioned, fingerprinting techniques do not modify the content, but calculate an identifier directly from the content itself. This is an obvious advantage when content is already available in a nonmarked version. Yet, this is also a drawback in comparison to watermarking schemes: personalization is not possible. Therefore, applications like leakage tracking are not possible. Although content can be tracked, tracking users is not possible, as content is generally not unique for individual users.

Instead of being marked, content must be registered. That means that only content can be identified if its fingerprint was previously calculated and stored in a database. And if the identifier is stored in a database, this database has to be accessible during the identification process.

Another limitation of fingerprinting techniques have to consider when using fingerprinting for controlling the data transfer networking infrastructure: encrypted content or scrambled content cannot be identified. Identification is only possible with content that is accessible as it is intended for rendering.

A comparison between the different properties of watermarking and fingerprinting is shown in Table 1.

Applications in DRM systems

Besides the previously listed applications of fingerprinting systems in automatic play list generation, broadcast monitoring, content tracking, and content flow limitations, another application is very interesting for fingerprinting techniques: royalty distribution. Content can be monitored in peer-to-peer networks with the help of fingerprinting techniques. This information can be combined with other information available, for example, metadata within the peer-to-peer networks used by humans for content identification. Keeping in mind the future revenue stream, new possibilities can be created when new technologies are considered, as discussed in the following section.

Summary

For each of the different basic technologies different realizations exist. This allows some flexibility for system developers in combining different solutions. For example, a DRM system can be implemented as an open source system. Nevertheless, this flexibility provides difficulties, especially for the compatibility of the different DRM systems.

From a security point of view, it has to be considered that the whole system is as secure as its weakest part. This does not only address the individual components but also their interactions. Thus, components, as well as their integration, have to be chosen carefully.

DRM TECHNOLOGIES

If everything seems under control, you're just not going fast enough.

Mario Andretti

Table 1. Principle characteristics of watermarking and fingerprinting schemes are summarised.

	Watermarking	**Fingerprinting**
Development	Has to be developed for individual media types	
Availability	Audio, video, images, 3D, music scores	Various media types with a focus on audio, video, images
Alteration	Content is altered by embedding	Not necessary but registration in database necessary instead
Registration	Not necessary (cf. alteration)	Prior to identification
Attacks	Vulnerable	Limited vulnerability (perceptual features)
Capacity	Varying on content (minimum requirement should be 64bit for creating a link)	Indirectly in the content and the method's ability to discriminate content
Infrastructure	Depending on application (can be implemented as an independent solution)	Needed (connection to a database)

In this section, the principle components of DRM systems are described. This general principle is more or less underlying each implementation of a DRM system. From an operational point of view, the typical parties involved are the content owner who distributes content, the customer or the consumer who purchases content, and a clearinghouse that manages licenses. For simplicity, we assume that the content owner is also the content distributor, which is not generally the case. If this is not the case, the relationship between the content distributor and the content owner might influence the DRM architecture, as content can be exchanged between these two parties at different security levels.

General Aspects

Sellers of traditional goods benefit from online shops as they are accessible without any time constraint. Product information as well as purchase related information can be made available. But not only traditional goods can be sold on the Internet. Especially content providers of digital content have a general interest in, and strongly benefit from, online distribution. Several advantages can be identified including:

- **Availability:** 24 hours a day and 7 days a week
- **Reduced costs:** Not only complete collections are sold
- **Try before buy:** Customers can have a prelistening/preview
- **Customer relationship:** Direct contact to customers like personalized offers, increased feedback possibilities, and so forth.
- **Reduction of shipping costs:** No physical goods have to be distributed
- **Reduction of storage costs:** Only a digital storage solution is need

Content providers deserve the protection of their content. Therefore content is encrypted before its distribution. As a result, this encrypted content can be distributed in various ways, including download or e-mail transmission. For content usage and rendering, a license is needed, which can be stored locally or on a remote server. This license is used by the client device or client player for decrypting content.

Today's protection solutions, however, are device dependent. Therefore content usage and rendering is device dependent. This is a general problem today. Customers do not want to be restricted by protection solutions. As most available distribution platforms strongly restrict customers (e.g., content can be rendered only on one certain device) in the numerous customers' view DRM is the acronym for digital restriction management.

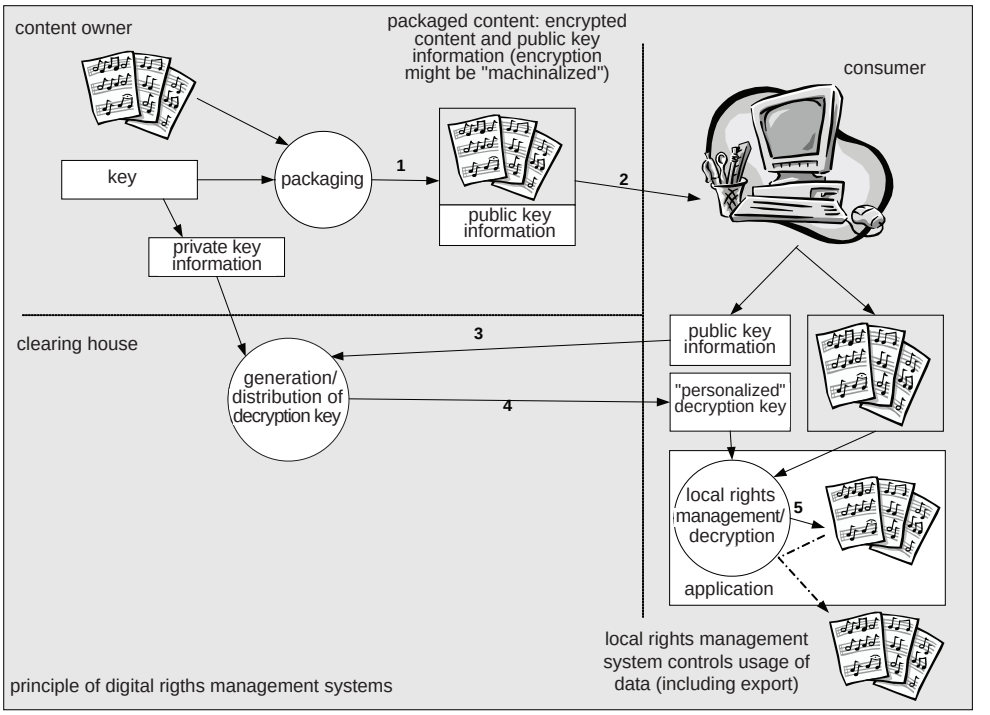
When analyzing a system's security, different assumptions have to be made as described by Arnold et al. (2003). These assumptions include the knowledge of the attacker. It is quite difficult to estimate this, as software patches ("hackz" or "crackz") can be often downloaded from the Internet ("break once, run everywhere"—BORE). These patches allow even users with almost no knowledge to circumvent certain protection mechanisms. Furthermore, the applied security solutions can be secure while the runtime system is not secure at all. This allows potential hackers to successfully attack the runtime system while not interfering with the applied security solutions. Thus, a secure system is vital for the security of content. Therefore the hardware industry is targeting at secure devices[20].

DRM Architecture

The general architecture of a DRM system is shown in Figure 7. Primary technology components can be identified (according to):

- Packagers[21] collect license information, metadata, and the requested content in encrypted files. These secure files are called packages, containers, and so forth.

Figure 7. This figure illustrated the principle architecture of a DRM system. The important aspect is that content is always encrypted outside of the DRM environment. Whenever an application wants to access information, the local rights management system is called to decrypt the content, and it also influences the functionality of the application. Thus a user cannot access any data outside the DRM system.



- Controllers[22] realize local rights management systems at the client side and are responsible for authentication of the device or the user, decryption of the content, provision of access to the content, and sometimes for financial transactions.
- License servers or clearinghouses are run by third trusted parties, and create and distribute licenses that grant access to the requested content via the local rights management system and can also contain access conditions.

As described by Rosenblatt et al. (2002), a broader definition of DRM encompasses everything that can be done to define, manage, and track rights to digital content. Thus further elements are included in this definition:

- Business rights (or contract rights) are typically associated with some content in certain scenarios. For example, the right to use a certain audio sequence in a commercial spot might be granted while processing of the audio sequence is prohibited.
- Access tracking, or tracking of operations on content, provides valuable information for content providers, even if they do not charge for access to the content. This information also helps to improve business models or relationships to customers.
- Rights licensing is an important issue, especially when content can be modified and is redistributed. Yet, technical solutions are strongly limited, for example, when the modification is translation.

Content Owner

Whenever content is distributed, this content is encrypted. The encrypted content is transmitted to the customer with public information about the encryption key. This process is called "packaging" and is step "1" in the figure 7. One has to keep in mind that this is just a simplified view on the package and the packaging itself. Typically, rights information is also included in the package to permit or to restrict certain types of operations, certain operations intervals, or the amount of operations, as well as additional product information (metadata). This rights information is stored in the license.

Content is stored in a repository. Either the repository is built within the DRM solution or it is part of a content management system (CMS). If a CMS stores the content and the packaging system is not able in managing arbitrary file types, the storage format of the content must be chosen according to the capabilities of the packaging respective the DRM system.

Again, it is also necessary to protect the content distribution system. Typical attacks might come from the Internet. These attacks can be faced by a well-configured firewall. Yet, attacks from users with physical access to the content distribution system are also possible. Thus, a certain level of trust in the people working at the content distributor's side is also necessary.

After packaging, content is distributed to the consumers. This can be done using different transmission channels. The Internet via download is probably the most common channel, but also, a transmission via e-mail, floppy disk, or CD is possible. The transmission processes is indicated in step "2."

Consumer

Whenever the consumer receives the content, it is initially useless as it is encrypted. Thus, the corresponding decryption key is needed. Of course it is possible to distribute the keys directly to the customer. Yet, this would reduce the security of the system drastically. Therefore, a local rights management component is responsible for this task. This component requests the keys from the clearinghouse (step "3"), which is a third trusted party. To increase the security, this local rights management component is unique and can be identified. Thus, personalized keys are sent to the local rights management component (step "4"), which makes them only useable for one certain local rights management component.

After receiving the decryption key the content is decrypted. For security reasons, neither the decryption key nor the decrypted content[23] must be stored locally.[24] Therefore, a strong connection between the local rights management component and the application rendering the content is necessary, as content exchange is not only possible via files but also through other channels, like the clipboard or via screenshots.

We would like to stress that the previously described functionality is not restricted to a personal computer. It can also be deployed in other devices. But certain ,for example, mobile consumer devices will result in certain requirements on the complexity of the involved algorithms as their computational power is weaker, and the usability of devices is directly correlated to the execution speed of certain operations.

One important aspect, not only when dealing with mobile devices, is the problem if the DRM solution should also be functional in an offline environment. This requirement increases security threats considerably.

Clearinghouse

The clearinghouse enables the consumer to render the content. The minimalist version transmits "personified" decryption keys to consumers. A more sophisticated version considers licensing issues: The valid content usage period or the amount of rendering. The clearinghouse is also

able to initiate financial transaction, for example, when pay-per-use is demanded in the license.

Rendering Applications

As described, a strong connection between the local rights management is necessary. Rosenblatt et al. (2002) distinguish different rendering applications: stand-alone, plug-in, and java rendering applications:

- Stand-alone rendering applications allow a maximum control of the content. Yet, this advantage has to be paid with several drawbacks: First, the software has to be distributed to the consumers. Second, the consumer has to install the proprietary software on his hardware. Generally, users prefer ready-to-use solutions. They do not want to be bothered with technical details.
- Plug-in rendering applications are common solutions that integrate themselves into existing software. As a direct consequence, the functionality of the "hosting" software is augmented. In the case of DRM plug-ins, it is able to render an increased number of files types. Of course, the plug-in has to modify the "hosting" software's behavior to control data exchange and to avoid any content leakage.

Unfortunately these solutions have to be developed for each hardware platform. From a content distributor's point of view, *Java* combines the advantages of stand-alone and plug-in applications, and additionally throws away the hardware dependency, as Java programs are not run directly on the microprocessor but are executed on a simulated processor, which is called the Java Virtual Machine (JVM). DRM solutions implemented in Java can be run on every processor for which a JVM exists.[25] Today this is the case for most Web browsers. Although Rosenblatt et al. (2002) raise the problem of incompatibilities, an efficient platform-independent DRM solution is currently addressed, for example, by Sun Microsystems.

Security Issues

The main purpose of a DRM solution is the protection of content respective of its license conform usage: content security. Security is always related to certain assumptions. For example, the described assumption of the technical skills of an attacker. But other security issues are directly related to the user and the involved hardware and software platforms.

Digital rights management systems for general content distribution scenarios require the identification of the user. For example, this is very important for secret information exchanged within a company. Similarly, an identification of a customer is important in the music distribution scenario as consumers can be seen as a business partner. For the business transaction, a credit card number might be sufficient. Practically, content usage cannot be limited to the person who purchased it. Thus, information about the person rendering the content is necessary. This information may be a simple e-mail address, a user ID, a password, or other personal information. In other application scenarios, biometric identification systems are used. For example, one can think of personalized mobile devices with biometric sensors: a "lost" mobile device is useless for its "finder." Yet, simple biometric solutions—and these are all current solutions which can be integrated into mass products for monetary reasons—can be easily fooled. Other solutions exist, like the "typewriting style," and are considered by music distribution solution providers. For identification, other possibilities include digital certificates (created by a third trusted party) or smart cards.

Besides user identification, device identification plays an important role. This can be done, for example, by a unique identification number or by the media access control (MAC) address.[26] The advantage of using the MAC address instead

of the IP address is the fact that IP addresses can be dynamic addresses, and also IP addresses can correspond to multiple users.

Device identification is not sufficient at all. One aspect that is generally neglected is the device integrity. The device integrity includes hardware as well as software integrity, which is very difficult. First, hardware and software are under total control of a user.[27] But even if the customer is trustworthy, "external influences" like Trojan horses might violate the device's integrity.

The problem of the device integrity is addressed by the "trusted computing" activities like the Trusted Computing Group (TCG, https://www.trustedcomputinggroup.org/), Trusted Computing Platform Alliance (TCPA, http://www.trustedcomputing.org/), or "Next Generation Secure Computing Base" (NGSCB, http://www.microsoft.com/resources/ngscb).

A trusted environment is typically assumed as a precondition. Yet, this is difficult to achieve, especially whenever the hardware and software cannot be fully controlled, which is usually the case whenever a consumer owns a device.

The trusted computing idea, which is supported by the most hardware and software players, aims to a standard for a PC with increased security level. Although this goal is very important in commercial scenarios (e.g., document security, information assurance…), such a standard is ambivalent for consumers. The danger is that control of individual hardware is transferred from the hardware owner to other parties, like the software vendor implementing the operating system or the content industry in general.

While this is interesting for content distributors, consumers might neglect this standard as from their point of view, the system is less trustworthy, and what is even more important, somebody has to pay for the additional components. The resulting trusted devices will not allow access to decrypted data, for example, through debugging software, will not start modified software, and they will also control the input and output devices.

Integrating DRM Systems with Existing Systems

Although DRM systems can be used as standalone solutions, it is more fruitful to combine DRM systems with other systems to maximize their common benefit. As DRM systems manage content access they can be used whenever content is involved. Thus DRM systems address the complete content "life cycle" and related tools or systems, including:

- Content Creation Tools
- Content Management Systems (CMS)
- Customer Relationship Management (CRM)
- Web publishing systems
- Access Control
- And so forth

In companies, a certain workflow process is established. As modifications of an existing workflow process is very expensive or maybe not possible, deploying DRM systems must not result in any change. This is even more important when techniques or solutions are applied for the protection of content. The protection level of some protection technology is time dependent; it might depend on the time and effort attackers spent in breaking it. If some content requires the highest protection level, the involved protection technology must be updated regularly. Therefore, changes of the workflow process are not manageable. But DRM systems must not only fit in the workflow process, but should also support it.

The general interest in DRM system is reflected in Microsoft's ambitious goal to include a complete DRM system within their operating system. However, there are strong concerns about the integration of DRM functionality in operating systems as discussed, for example, by Anderson (2003, 2004) and the Electronic Frontier Foundation (EFF, http://www.eff.org/).

Content Creation and Management

In business application scenarios dealing with content creation and management, DRM technology can be integrated in the content creation tools and the content management system. The main motivation for this is that content is always stored together with metadata. This metadata may include contract rights or licensing rights.

As an alternative, rights metadata can be created by a manual input. Yet, manual input is expensive as well as error-prone. Thus, a DRM system allows the automation of metadata creation and guarantees its consistency, even if compound works are created. For example, an audiovisual presentation might contain several individual images, video sequences, songs, and speech, which have their individual rights. Content creation and authoring software involving a DRM system can automatically deal with these rights issues, and also solve problems when extracts of such a kind of audiovisual sequence are created.

Besides the storage of rights in a DRM system, fingerprinting and watermarking technologies can link media to the corresponding set of rights. Thus, even a link between the rights and the rights is possible when a media break happened. These content management systems (CMS) integration issues are addressed by Rosenblatt and Dykstra (2003a, 2003b).

Web Publishing and Customer Relationship Management

Deployment of DRM solutions in consumer-related areas typically involve the sales of digital content. This has to be done via an online catalogue or portal. DRM solutions provide the necessary technologies to achieve different business models that better suit the wishes of customers. These business models may include subscription-based services, free time-limited trials, or pay-per-rendering, and can be chosen independently for different customers.

Further improvements are possible when DRM technologies are integrated with customer relationship management systems. Therefore, the offers can be chosen, exactly matching the customers' behavior. For example, whenever a customer purchases a rendering right for a certain content, free time-limited trial rights can be created for related content. Also, the prices for products can be adapted to the usage, allowing a subtle change between pay-per-rendering and subscription based services, for example, as addressed by Rosenblatt and Dykstra (2003a, 2003b).

Access Control

Access control is a desired criterion for content providers and contet owners. Yet, this is not a desired criterion for customers, as they generally do not accept any restrictions on content they purchased. Additionally, access control might interfere with privacy, as discussed by Cohen (2002) and considered by the EU in "Digital Rights—Background, Systems, Assessment."

This is different from companies that want to keep confidential material within their domain. Thus, enterprise content management (ECM) can be regarded as an application that very strongly demands efficient rights management systems. NGSCB and TCG lay the necessary foundation for a secure environment within business applications.[28] As the computers involved in this area are under the control of one administrator, the security assumptions within this scenario are different from the previous scenario. Also DRM systems do not interfere with privacy in this scenario. But DRM systems might interfere with other laws, as access to information can be limited to a certain time interval. And not to forget that also companies, like users, want to define when content is accessible. Both will not accept restriction imposed by third parties, which includes hardware and operating system developers.

Examples for Conflicts between Security and Consumer Issues

Here, two examples are given how the security intention of DRM systems can interfere with consumer issues and sometimes even with law. These incompatibilities can be created artificially for the protection of content, for example, in the case of Macrovision. Also, a proprietary format can result in incompatibilities, for example, in the case of Sony.

- Macrovision's video copy protection system (http://www.macrovision.com/) is a popular product for protecting video content. It was originally developed for video home systems (VHS). An additional copy protection signal is inserted in the part of the video signal used to control the TV (vertical blanking interval and extra synchronization pulses). The idea is that this kind of noise does not interfere with the screen representation of the visual content. But if a video cassette recorder (VCR) tries to make an exact copy of the video signal containing the copy protection signal, it will fail drastically (for the visual content). Interestingly, this idea worked fine with TVs produced before Macrovision's protection system was developed. However, with the growing numbers of DVD devices, people found out that for some TV sets, the only possibility is to connect the DVD to the screen via the VCR. Although the signal is passed only through the VCR in this case, some activate their video-scrambling chip, leading to the same distortion as descried earlier. Additionally some TVs are not capable of resolving the Macrovision signal due to the bas synchronisation pulses. And the Macrovision's video copy protection system delayed the development of DVD players with a progressive[29] output signal.
- Not only Apple with iTunes insists on proprietary format and unrevealed applicaton programming interfaces (APIs); also does (or did) Sony. BETAMAX is an example where Sony failed with a proprietary format. Sony founder Akio Morita saw the reason in the missing license possibilities, resulting in the fact that the inferior VHS system reached a critical mass. Besides BETAMAX, MicroMV was another proprietary format that was abandoned, although it was introduced recently in 2002. Another proprieraty format is ATRAC3, Sony Minidisc format. Even the memory sticks used in Sony's digital cameras and PDAs are proprietary.

Incompatibility, as it regularly has happened with Macrovision's video copy protection system, is also an issue for the protection of music CDs. Incompatibilities interfering with a trouble-free enjoyment led to the creation of "negative lists" like UnCD (cf. http://www.heise.de/ct/cd-register/). Proprietary formats are always critical. For example, Microsoft Office documents can hardly be exported to software products produced by other vendors. But for protected content, this is even more critical. On the one hand content encryption parameters have to be known. On the other hand the representation is unknown.

Potential problems can be foreseen not only in the case of a proprietary format: Customers will not be happy if a proprietary format is abandoned. But furthermore, there is one aspect that is never considered by industry. Archives must provide access to content, even after years of its creation and distribution. They will fail poorly. Today it is already a problem to access content in old formats stored on outdated devices, as hardware and software for access is missing. This problem will become much more severe with encrypted content whose decryption keys are not accessible anymore.

Further Criteria

In addition to the previously mentioned characteristics that should be considered, further criteria that should be evaluated include:

- **Degree of protection:** As described before, one has to be clear who the potential attackers are and what kind of attacks can be performed. On the one hand, typical customers should not be able to break the system. On the other hand, commercially oriented product pirates should not be able to attack a DRM-system successfully. Both groups can be distinguished by their knowledge and the available tools. Especially for commercially oriented pirates there is almost always a possibility to break the security of a DRM-system, as they expect a monetary benefit. Firstly, they can hire professional security experts[30] who have the necessary knowledge. Secondly, they can buy the necessary equipment. Therefore, a huge variety of attacks can be performed, including attacks penetrating hardware.[31]
- **Known attacks:** Considering the security of DRM-systems, one important question is: Are there any known attacks against the complete DRM-system or against individual components? As any DRM system is as strong as its weakest component, one has to consider this aspect carefully. In some cases the weakest points might even be humans. For example, if people are interested in hacking a server, sometimes the easiest way might be to bribe its administrator for creating security holes, which can be exploited easily. Besides the knowledge of successful attacks, details about the attack itself are important, including the effort and the consequences. On the one hand a successful attack might take a lot of time, involve expert knowledge, and has to be performed on each digital item. On the other hand an exploit of the system might have been discovered, resulting in a software patch available on the Internet. Balancing the negative effects, it is obvious that the second kind of attack is much more severe and might almost destroy the security of the whole DRM-system. This is not a theoretic or potential threat. The software industry experienced that hackers[32] react fast and sometimes publish new exploits within a few days in the Internet.
- **Usability:** Any hindrance to content access caused by DRM systems directly reduces user acceptance. Thus, an ideal DRM-system should not be experienced by any user unless a user has the intention to violate the licensing conditions. Unfortunately, this is practically not realizable, as operations cannot be qualified in (current) DRM-systems. For example, a DRM-system cannot distinguish between a legal[33] format conversion and an illegal one. As a consequence, a DRM system prevents all operations that potentially lead to a violation of licensing conditions.[34] One of these effects is the denial of copying in DRM-systems, leading to strong impacts on accustomed ease of handling content.
- **Compatibility:** An important aspect of usability is compatibility. The rendering of content should not be limited to a specific class of devices. This is a major obstacle of today's DRM systems. Although there are ongoing standardization issues, no compatible DRM exists yet.
- **Current popularity:** Obviously, content owners and distributors are in favor of DRM as it supports them in protecting content. Due to restrictions imposed by DRM systems and due to privacy issues most users are against DRM systems. However, the success of iTunes shows that DRM solutions, which are not as restrictive or obvious, are acceptable for customers.

- **Future trends:** DRM is a relatively young issue and one which addresses not only rationality, but also feelings. Also little experience was gained so far with its application. The development of new DRM systems with different kinds of restrictions will show what will be acceptable for customers, practically.

Summary

Obviously, DRM covers a wide range of technologies and also touches legal issues, which makes this topic quite complex. DRM's main purpose is the protection of content. Content security is a very important issue, although not easy to achieve. As a consequence, operating systems implement more and more functionality needed for the protection of content. Their initial implementations, TCG and TCPA, experienced strong resistance, for example, as privacy and traditional content usage are not guaranteed. Nevertheless, there are a lot of hardware systems, especially laptops and mobile phones, that already include the basic functionality. This is almost unknown to most users as this functionality is not used yet.

As explained before, user acceptance is very crucial for the success of business models as well as for the success of DRM systems. Among the important aspects is compatibility and traditional content usage. This does not mean that customers will not accept DRM. Apple shows with its iTunes Music Store—it has a less restrictive content protection policy—that customers indeed are actually willing to pay for DRM-protected content. Nevertheless, iTunes is under strong discussions due to its restrictive DRM solution, from a legal point of view, for example, as in Norway or in France.

TECHNOLOGICAL POSSIBILITIES AND PRACTICAL LIMITATIONS

In dreams and in love there are no impossibilities.

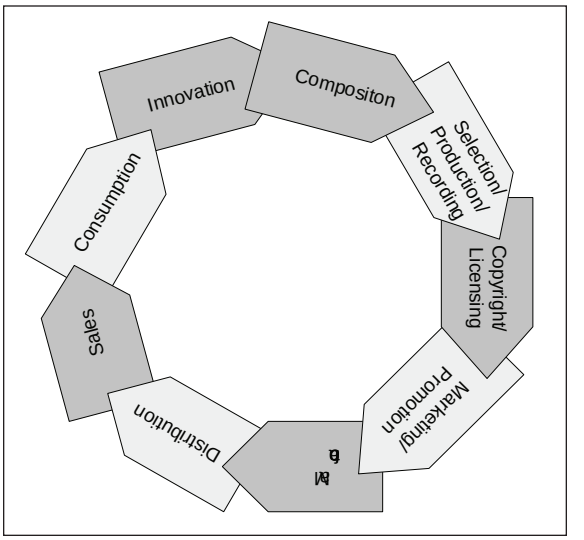
Janos Arany

Content distribution depends on the underlying business model. Therefore, the objective of this section is to describe how DRM can support different business models. For further information, the reader is suggested to consult Rosenblatt (2002), Dubosson-Torbay et al. (Dubosson-Torbay, Pigneur, & Usunier, 2004) or Bockstedt et al. (Bockstedt, Kauffman, & Riggins, 2005).

Traditional Music Industry Value Chain

A simplified traditional music industry value chain is shown in Figure 8. Its purpose is to exemplify the influence of digital representation and DRM

Figure 8. The traditional music value chain involves different players for composition, selection, production, and recording, copyright and licensing, marketing and promotion, manufacturing, distribution, sales, consumption, and innovation.



on content distribution. For specific content like audio or sheet music, the content value chain varies. Different chain links can be identified in the general content value chain:

1. Composition
2. Selection, production, and recording
3. Copyright and licensing
4. Marketing and promotion
5. Manufacturing
6. Distribution
7. Sales
8. Consumption
9. Innovation

This value chain can be considered as a value circle: Existing content is typically the starting point for innovation, which is already the case for the traditional value chain.[35]

Digital Music Industry Value Chain

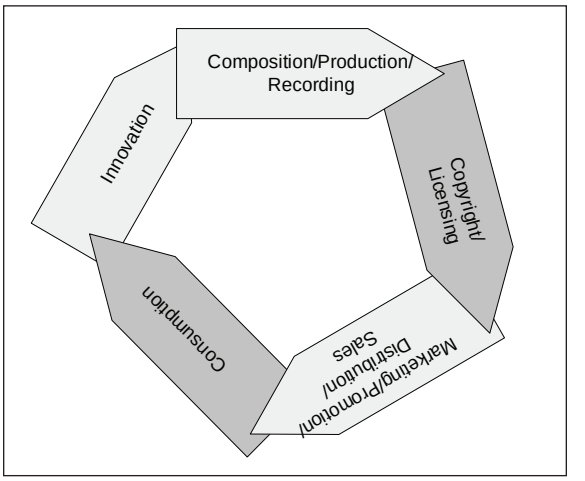
The digital content representation strongly influences the production and distribution of music. Music has become or is becoming a digital good. As a consequence of the digital representation of music, the processing and distribution possibilities are extended. These new possibilities not only blur the boundaries in the traditional content value chain. The result is a downsized content value chain, as shown in Figure 9:

1. Composition, production, and recording
2. Copyright and licensing
3. Marketing and promotion, distribution, sales
4. Consumption
5. Innovation

Influence of DRM on the Digital Music Industry Value Chain

In Figure 9 we showed the influence of digitalization. DRM provides further potentials

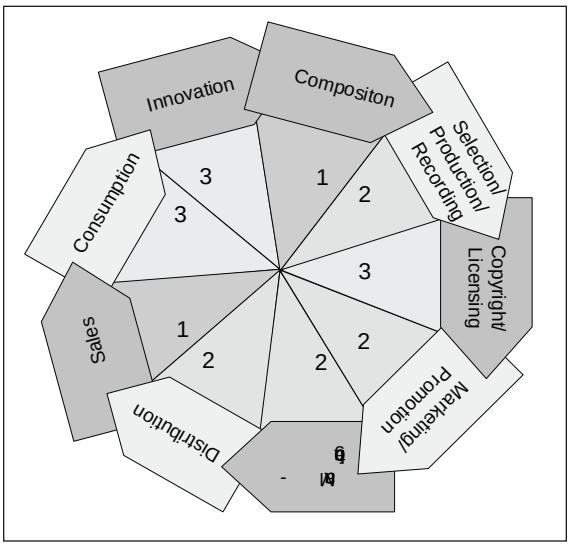
Figure 9. The digital music industry value chain is downsized through the possibilities of digital content representation and its distribution. From content and rights owners' point of view, this allows more efficient content distribution to customers. Furthermore, due to the loss of hardware costs and the capabilities of the computers, more tasks can be performed with less equipment. Obviously, the cycles are rigorously shorter than in the traditional content value chain.



for content creators and content owners: DRM enables control on content usage. Thus content consumption and innovation can be influenced or controlled with DRM. As the basis for DRM are digital (representation of) license, copyright and licensing can be simplified, also as shown in Figure 10. This is so far ongoing development. For example in the AXMEDIS (http://www.axmedis.org) project, the simplification of licensing issues is a central aspect.

Traditionally, a content creator benefits from the composition of the new content and its sale or derived contents thereof. Due to the digitalization, the content creator benefits as selection, production, and recording, marketing and promotion, manufacturing, and distribution is easier and more strongly connected. DRM furthermore has potentials in copyright and licensing, consumption, and innovation. This is shown in Figure 10.

Figure 10. Influence of digitalization and DRM on the content value chain: Traditionally, a content creator benefits from the composition of the new content and its sale or derived contents thereof (labeled with "1"). Due to the digitalization the content creator benefits as selection, production, and recording, marketing and promotion, manufacturing, and distribution is easier and more strongly connected (labeled with "2"). Due to DRM, potentials can be exploited in the areas copyright and licensing, consumption, and innovation (labeled with "3").



Business and License Models

Different business and corresponding license models can be implemented considering the potentials of digital distribution and DRM. The common ones are listed. Further business and license models are described by Dubosson-Torbay et al. (2004). They focus on the influence of emerged P2P legal distribution of free content and illegal distribution of copyright protected content:

- License per content and license per collection of content (paid downloads).
- License per rendering (pay-per-view, pay-per-listen, …).
- License for a specific number of renderings or for a specific time frame.
- Distributed retail by distributing content to retailers (super distribution).
- Super distribution in P2P environments.
- Subscription based services.
- License according to usage.

Licensing Rights

Instead of distributing the content, the rights can be "sold." Of course digital rights management also should address these business models, as selling rights involves rights transactions among commercial organizations.

Summary

DRM provides the possibility to implement a different business model, for example, based on the content consumption. The success of DRM-enabled business models is decided by the customers' acceptance. Furthermore, a successful DRM solution supports business models and does not require the business models to be adapted to the DRM system.

Practically, it does not matter if the business models are adopted models from the physical world, new business models, or a combination of both. Naturally, the business models must be derived from the needs of the customers, which is a well-known fact from the physical world. Yet, new technologies provide possibilities for further products and services.

It should be also stressed here that only few content creators' primary income in the music domain is based on the commercial distribution of their music or songs. A huge part lives on secondary sources, like live performances or ring tones. Thus, limiting access to content is not in the interest for these artists. As a consequence, each artist has to decide carefully the personal

pros and cons before applying existing DRM technologies to her/his content.

TOWARDS THE CUSTOMERS

All government—indeed, every human benefit and enjoyment, every virtue and every prudent act—is founded on compromise and barter.

Edmund Burke

Although music labels were strongly in favor of CD copy protection technologies, more and more music labels do not apply CD copy protection technologies anymore. Users did not appreciate this technology that they practically realized as an obstacle.

This is something content owners and distributors have to understand. Maybe the following statement explains the users' restrictions best: "I will accept your DRM protected content if you accept my DRM-protected money!" Thus, new solutions are needed considering the customers' requirements and objections. Similarly, the decision of a French court against DVD copy protection shows that new approaches have to be developed. In this section, we summarize recently developed and on-going developments that better consider customers' requirements.

Obviously, DRM and content protection is still a hot topic. But as shown by Apple's iTunes MusicStore, and some others that want to get a share from Apple's success, users potentially accept content protection technologies. Nevertheless, there are ongoing developments that focus on the user requirements that have not been sufficiently considered yet.

Interoperable DRM

One of the major reasons customers are very reluctant against it is compatibility, respectively, the lack of compatibility. "Buy once, listen anywhere and anytime" is not possible with current DRM systems. Actually, this was one of the reasons why customers reject copy protected CDs: They cannot be played on all consumer devices (including computers).

In the digital world the situation is even more complex: Having different storage carriers, different media encodings and recently, different DRM containers dramatically increases the difficulties in exchanging content.[36] And for ordinary users this is a big issue: they are interested in enjoying content; they neither want to be bothered with any technical detail nor with any problem.

As described before, there are ongoing efforts that address compatible DRM, which we include:

- **CORAL:** The Coral Consortium is "a cross-industry group to promote interoperability between digital rights management (DRM) technologies used in the consumer media market. The Consortium's goal is to create a common technology framework for content, device, and service providers, regardless of the DRM technologies they use. This open technology framework will enable a simple and consistent digital entertainment experience for consumers." (http://www.coral-interop.org/)
- **DMP:** The Digital Media Project is a not-for-profit organization with the mission to "promote continuing successful development, deployment and use of Digital Media that respect the rights of creators and rights holders to exploit their works, the wish of end users to fully enjoy the benefits of Digital Media and the interests of various value-chain players to provide products and services." (http://www.dmpf.org/)
- **ISMA:** The Internet Streaming Media Alliance's goal is "to accelerate the adoption and deployment of open standards for streaming rich media content such as video, audio, and associated data, over Internet protocols." (http://www.isma.tv/)

- **OMA:** Open Mobile Alliance is similar to ISMA, which is not limited to a specific technology, but is in favor of a certain range of applications, OMA wants to promote the usage of mobile devices. Its mission is "to facilitate global user adoption of mobile data services by specifying market driven mobile service enablers that ensure service interoperability across devices, geographies, service providers, operators, and networks, while allowing businesses to compete through innovation and differentiation." (http://www.openmobilealliance.org/)

Unfortunately, there is a competition between the different standardization activities. It is very interesting to see how the different standardization activities developed during the last years a good summary is given by Rosenblatt (2004, 2005, 2006, 2006b).

In the mobile area, OMA so far succeeded in the sense that new mobile phones already integrate OMA-DRM. The new extension of OMA addressing entertainment devices at home thus seems promising, although OMA seems to have slowed down. DMP seems to lack a user group and electronics companies, and still is in the specification phase in contrast to CORAL, which already showed how to build interoperable DRM, for example, with Microsoft Windows Media DRM. CORAL would benefit from Apple that should publish their interfaces. In addition to these activities, Sun initiated a project called Open Media Commons (http://www.openmediacommons.org/). For this open source "DRM/everywhere available" (DReaM), no license cost should limit its usage. If a reliable security level can be guaranteed in open source, DRM has to be proven in the future. The first implementation, however, is already limited to IPTV. The first implementations are expected in 2007.

Less Interfering DRM

Developing interoperable DRM systems is only one direction for improving the usability of DRM-protected content. Another direction is not to develop new formats and devices, but to use existing formats and embedding customer information. This has been described before as transaction watermarks.

One example for this is the Light Weight Digital Rights Management (http://www.lwdrm.com/), which cooperates with consumers. It distinguishes between locally bound and signed content in which user certificates are enclosed. As these user certificates link the content to users, users are expected to be very reluctant in distributing this personalized content.

The philosophy behind this is quite simple, like the car's license plate: In principle, the users can do anything with their content. There is no restriction unless the content is not distributed to others. If such personified content occurs on illegal file sharing networks, the responsible user can be identified and blamed for this. This is similar if a driver violates a speed limit and can be punished for this.

Besides the usage aspect—traditional content usage is not prevented—user awareness is increased: Users become responsible for the content they purchase.

New Developments in P2P-Networks

There are also ongoing developments that try to commercialize the distribution in P2P networks. One approach is to distribute DRM-protected content via P2P networks. Examples are Napster (http://www.napster.com/) for audio content or in2movies (http://www.in2movies.de/in2movies/) for video content. Besides these traditional approaches, new developments that avoid classical DRM protection methods have been developed.

Music2Share

Kalker et al. (Kalker, Epema, Hartel, Lagendijk, & van Steen, 2004) presented a solution where each client integrates fingerprinting and watermarking techniques. By this the system allows the identification of the content exchanged. Simplified, before a client is allowed to receive content, his/her request is evaluated from a trusted third party to identify, if he/she already licensed the content. If so, the content is transferred to the customer. This allows putting different business models on top of existing P2P networks. After receiving the content, the content is encrypted or put in a DRM container, together with the licensing information retrieved from the TTP. Again, users experience restrictions when content is DRM protected.

The "Social Distribution Network" (SDN)

User awareness and user responsibility are the key concepts of the so-called social distribution networks (SDNs), as presented by Schmucker (2004) and Schmucker and Ebinger (2005a).[37]

The authors motivate them by the following train of thoughts:

- Perfect content protection is not possible. There are always security leaks like the analog hole. This has to be considered when efforts are spent for the development, integration, or usage of DRM. This means that at least specialists "unprotect" DRM protected content.
- Content exchange via the Internet cannot be controlled.
- Unknown artists do not care about DRM and illegal distribution, as their primary income is not from record sales but from performances, ring tones, and so forth. Nevertheless, they deserve a platform for the exchange, and especially the promotion of their content. This platform requires the possibility to stop the delivering of content upon request.
- Users are not bad. Costumers will not redistribute illegal copies to harm artists. Instead they are willing to pay a reasonable amount of money for music that is unrestricted in its usage.
- Costumers will support artists by promoting content. Additionally, they will create additional metadata. This additional metadata further promotes artists' content.

Commercial DRM-protected content is less attractive and competes with illegally distributed content that does not have any usage limitations.

A distribution system that integrates consumers is most attractive if it is based on P2P networks: "Let them make work (pay) for you" is the direct benefit for artists. P2P users pay for storage and bandwidth. A P2P-based architecture was presented by Schmucker and Ebinger (2005b) that considered those issues mentioned earlier,and provides a framework for the secure exchange of unprotected content.

Everybody who is registered can distribute content in the P2P network. User awareness is a central issue. It is achieved by the feedback to the customers: If the content that should be distributed is already registered as nonsharable, the user gets a message and cannot distribute this content. In contrast, if this content is not registered, the user has to register it to him/her. After this registration, content can be distributed freely within the P2P network.

Due to the fact that content itself is not DRM protected, this distribution network is very interesting for the promotional distribution of content, especially for relatively unknown artists.

New Licensing and Business Models

In addition to the technological developments, new licensing and business models are being

developed. In general, they are not limited to a certain distribution channel. Some of them are presented here.

Super Distribution

The Potato-System (http://www.potatosystem.com/) and WeedShare (http://www.weedshare.com/) are typical super distribution business models. The users who distribute content of artists get money for the distribution if the recipient buys the music.

Creative Commons

Creative Commons provides a set of copyright licenses free for public use. (http://creativecommons.org/). One can select a suitable license easily, based upon some preferences/selections. This license model is related to GNU Public License (GPL) and EFF Open Audio License. Some projects evolved from creative commons like science commons (http://sciencecommons.org/) or iCommons, which aims at a "united global commons front" (http://icommons.org/).

Fisher's License Model

Fisher's license model is based on a low-rate subscription. Fisher (2004) showed in detail how such a model could work, and Orlowski (2004) analyzed it.

German Academic Publisher

German Academic Publishers (http://www.gap-portal.de/) is developing a new model for the design and administration of electronic publications. It is especially interested in the scientist's need for "Open Access."

Summary

Customers' acceptance is the most critical issue of content protection technology. Thus, current developments try to solve today's systems' flaws. An interesting aspectsis to raise consumers awareness and their responsibility, while incorporating them in the distribution of content either buy online reputation systems or by using their resources. There is a huge potential in the user communities, as examples in other areas show. Interestingly, the successful content distribution platforms, like YouTube (http://www.youtube.com) or BeSonic (http://www.besonic.com), incorporate users in producing, rating, and ranking content, but not in its distribution.

Return on investment (ROI) or return on capital employed (ROCE) plays an important role for nonprofit as well as for commercial organizations. Both judge solutions' and technologies' benefit according to their ROI. ROI is even more important if venture capital is involved, or a company is listed in the stock market.

One problem of general security solutions is to measure this return on investment. Costs for new technology can be measured accurately, but what about the saved amount of money? The problem return on security invest (ROSI) is currently highly debated.

As DRM belongs to the category of security mechanisms, the same problems arise here. Yet, additional return on investment factors can be identified:

- Cost saving resulting from electronic stock.
- Cost saving resulting from traditional content delivery (including packaging or redelivery).
- Flexibility and scalability of the online solution (business model can be changed or adopted easily).
- Improved services to customers (e.g., availability, transmission speed, …).

- Improved customer relationship management.
- Improved monitoring capabilities.
- Improved brand loyalty.

Again, these returns are difficult to measure. But it should be clear that the benefit of a modern combined distribution and DRM solution is far beyond the return on investment by protection of content after the point of purchase.

Bomsel and Geffroy (2004) characterized the economic characteristics of DRM. Two main economic functions of DRM are defined: content protection and versioning. Then, the mechanisms of DRM adaptations are analyzed. Network effects are considered in this analysis. Interestingly, this analysis distinguishes between open and dedicated networks for content delivery. For example, mobiles are considered a one-way dedicated channel for content delivery. Although the analysis identified the DRM's significance for content delivery, three obstacles are identified for DRM's roll-out in open architectures (in contrast to dedicated networks).

1. "The current economic model of Internet access … does not favour non free open services."
2. "In broadband networks, pay content distribution conflicts with the network effects pulling the roll-out."
3. "Content owners may push alternative networks."

According to Bomsel and Geffroy (2004), one consequence is that "broadband open networks may give priority to two way communication services … rather than to pay models for digital media content distribution."

THE FUTURE SOLUTION

Again we would like to emphasize that DRM systems integration within other solutions, like content management systems, will increase their benefit most. Aspects that cannot be neglected in the design and decision process include the business models and the workflow process. Depending on the customers, a less-restrictive DRM, for example, lightweight DRM, might even be the better solution.

The change in the hardware and software solutions for content distribution is still ongoing. Their tendency is going into the direction of "trusted computers" or "trusted devices." Independently how long it takes to achieve these ambitious goals, which have some advantages and also some drawbacks, customers have to accept these solutions and also to pay for them. This development towards "trusted devices" is highly debated, as it seems to endanger the right for "free speech" and free information exchange. Future solutions of trusted computers might allow the customers a more flexible key management away from hardware keys stored in machines, but with keys stored in smart cards. This will also be influenced by other standardization activities like DMP, OMA, CRF, or CORAL.

So what the future might bring is hard to say, as history already told us that not the best solution must succeed in the long run.[38] Nevertheless, GartnerG2 and the Berkman Center for Internet & Society presented "five possible scenarios for copyright law applicable to digital media in the United States" in the report "Five Scenarios for Digital Media in a Post-Napster World." These scenarios predicted losses and gains for consumer values, and costs and revenues for content owners, artists, technology CE vendors, and Internet service providers:

1. The no-change scenario is based on the assumption that DMCA is still enforced: "This scenario is the least likely to play out, as the entertainment industries are not likely to sit still and see their business models slowly destroyed. Media companies have already attempted to address piracy via legal, regulatory and technology solutions. They will continue to pursue solutions to what they perceive as an attack on their traditional business models. However, it is likely that the no-change scenario will prevail in the immediate future as efforts so far have yielded minimal results and piracy is still widespread."
2. The taking property rights seriously scenario is based on the assumption that content owners and providers strongly succeed in protection of their IPRs. As a result, the gains for content owners and artists will increase together with increased cost on the overhead with violation prosecution. Technology and Internet service providers will gain marginally and the consumers will be the losers. "This scenario certainly plays to the interests of those in the media industry and copyright holders who would seek to maintain existing business models based on complete control of the content. However, it is probably the one scenario that best illustrates the chasm separating content owners/media companies from large segments of the consumer population. It is also the scenario that, if realized, would most emphatically underscore the regional differences in intellectual property laws and enforcement. "
3. The effective technology defense scenario assumptions are that content will be distributed physically and digitally. Content is copy protected while still meeting consumers' needs. It also includes the assumption that copy protection is an ongoing cycle, which is indeed the case. "This scenario can be described as 'technology rescues the content industries from wanton copyright piracy.' However, the technological challenges are compounded by the numbers of increasingly tech-savvy consumers around the world. There is very little margin for error and the transition to universal copy protection must be relatively quick. Otherwise, media companies and artists may find that large numbers of consumers are seeking digital content from sources other than traditional music labels, movie studios and publishers." The difference between this scenario and the second scenario is that the second scenario assumes legal reforms while the third scenario assumes technological changes.[39]
4. The compulsory license scenario assumes that the current copyright system is replaced by a system in which the creators and producers of content are compensated by the government in proportion to the "consumption" frequency. "While this scenario has its own risks—giving a government entity significant discretionary power and assuring the virtual annihilation of the physical retail market—the potential for reducing litigation, lowering the costs of enforcement and eliminating the incentive for an ongoing encryption 'arms race' make it very attractive."
5. The utility model scenario considers digital content as a public utility. Regulations are enforced by a federal regulatory body. Concerning the estimated effects, this scenario is most interesting. "Of all five scenarios presented here, this one countenances major legal, business and consumer behaviors changes. From a technology perspective, it is less complicated than might be considered. At least one technology provider currently has an offering that could track content distribution to the end user in much the same way power companies use meter-reading systems. However, music and

> movie producers and their businesses—not to mention conventional retail distribution entities—will be violently opposed. Music and movie producers would see their revenue models altered greatly, with the costs associated with distributing content and usage eliminated."

Thus the "utility model scenario," as described in the report "Five Scenarios for Digital Media in a Post-Napster World" by GartnerG2 and the Berkman Center for Internet & Society, might be the best solution to the current problem of the content owner. But before such a final solution is publicly accepted and established, content providers have to find their individual solutions.

The Evolution of P2P Networks

P2P technology is constantly evolving. Thus, it is interesting to see what will be the next step in this evolution. Biddle et al. (Biddle, *England, Peinado, & Willman,* 2002) from Microsoft expect that "interconnected small world darknets" will come into existence. In this network type, small groups of people exchange content within. The different groups are connected through people being a member of several groups. Due to the structure, it is very difficult to control and therefore to stop exchange within it.

This development has gone far beyond from shared file systems. Friendster (http://www.friendster.com/) indicated this development and was also one of Napster's success factors according to Roettgers (2004): Communities were part of Napster. And solutions like AllPeers (http://www.allpeers.com/) enable content sharing with friends and family directly via a Web browser plug-in.

Current P2P rather satisfies the users' need for anonymity due to the legal pressure. "The Free Network Project" (http://freenet.sourceforge.net/) is probably the P2P network addressing this requirement for anonymity best. It "is entirely decentralized and publishers and consumers of information are anonymous. Without anonymity there can never be true freedom of speech, and without decentralization the network will be vulnerable to attack." Although its intended aim is to stop censorship, it can also be misused for illegal content exchange. And other developments are ongoing as well.

This is in contradiction to the trust-based communities like Friendster. Incorporating trusted communities in P2P networks will result in "social P2P networks." They will exist in parallel to the anonymous P2P networks.

Besides legal measures and court trials, the evolution of P2P technology also resulted in the evolution of technology, which can be used as countermeasures against illegal distribution. One popular approach is the introduction of wrong or manipulated files in the P2P networks. Fingerprinting solutions are used in commercial and educational environments as well as in the P2P-networks, for example, in Napster. Also, the Internet traffic is statistically analyzed to identify potential P2P applications. Early 2007, YouTube announced that it will also deploy fingerprinting technologies for IPR protection.

Instead of fighting P2P networks, advantages are more and more realized. For example, P2P networks can be used for promotion of new material. Additionally, P2P networks are a distribution channel, as recently used by George Michael. Furthermore, content is exchanged between people. Statistical analysis can be performed on this exchange with the aim to identify new trends in music, as done by Big Champagne (http://www.bigchampagne.com/).

The Analogue Hole

DRM developments aim at trusted systems: Systems that cannot be "manipulated" by users. But there is a general flaw in trying to protect content: the analogue hole. There must be a version of the content that can be accessed by humans: Images and videos are visualized and audio is played.

The resulting signal, which is intended for human spectators or listeners, can also be recorded in a digital format again. In this case, watermarking, if it is sufficiently robust, presents the only possibility to trace back the origin of the leakage. This might not be possible somewhere in the future, when electrodes directly stimulate the brain. But in the meantime, an analog signal has to be presented to the ears or the eyes.

There are already companies trying to address exactly this problem. For example, DarkNoiseTechnologies[40] tries to insert a "dark noise" in the signal, with the aim that recorded versions of the signal suffer severe distortions.

Examples for Music Distribution

Within this chapter, an overview about the technological aspects of audiovisual protection was provided. As already discussed, protection solutions have to form a unity with other technologies, for example, CMS or CRMS, in distribution systems. Different online music distribution services are described in several reports at the Interactive Musicnetwork (http://www.interactivemusicnetwork.org).

All of them apply DRM technology. Although in the case of Apple iTunes MusicStore, the DRM is less restrictive and allows burning CDs. Maybe this is one of the reasons why Apple's approach is the most successful so far.

Summary

In spite of all efforts, the current situation is controversial: From a consumer's perspective, any usage restriction reduces content value. From a content owner's perspective, digital content cannot be distributed without any protection. Hence, a compromise must be found between the consumers and the content owners. So far DRM is not generally accepted.

Nevertheless, DRM has the potential to be part of this compromise. For example, the versioning, as identified by Bomsel and Geffroy (2004), provides interesting opportunities. However, the content owners have to be aware that the new possibilities in usage control that are offered by DRM, are neither wanted nor enjoyed by customers today. It seems that in early 2007, the music industry realizes the problems caused by current DRM systems. But alternatives that are attractive for content owners and customers so far are still missing.

Thus, each content owner has to perform an objective analysis on the individual DRM usage. This analysis has to consider his/her needs and the needs and the requirements of the customers as well. Only by this, realistic opportunities can be identified in contrast to the hopes and expectations that were initially created by technology developers. Only then, DRM has realistic chances to be a valuable technology.

Not to be forgotten, that technology is often used in different ways, as initially intended by its developers. The potentials and the future usage of DRM might also be different from its initial intensions. Thus, continuously analyzing new application scenarios and technologies that were initially not covered by DRM technology is mndatory.

ENDNOTES

1 For example, in the U.S., the copyright for a new composition lasts for the lifetime of the composer and additional 70 years after his death.

2 Generally, user anonymity is not given. All users can be traced back by their IP and with the support of the ISP. It is very important for wireless-LAN (WLAN) operator to secure access to their WLAN against misuse, as these operators are responsible for any kind of misuse.

3 Fair use is a statutory exemption to the copyright law.

4 Interestingly, the existing solutions analysed by Camp, which included copy protection as well as circumvention technologies, only partially fulfilled these requirements.

5 The analogue mass production ensured that a document survives unaltered and can be located.

6 The publishers' and broadcasting investment results in a careful selection of content.

7 An information collection is available at RIAA (http://www.riaa.com/).

8 Freenet can be summarized as a decentralized network of file-sharing nodes tied together with strong encryption and further technology, which allows anonymous users.

9 Besides confidentiality, other relevant aspects might be authentication, integrity, or copyright protection, which has to be addressed using different techniques.

10 Yet this distinction is somewhat hazy as block ciphers can be used as stream ciphers, and vice versa.

11 These algorithms are also known as one-way hash algorithms.

12 Typically a soft-hash or perceptual hash value is embedded, which is another term for fingerprinting.

13 A watermark in an image or audio can be used to start a plug-in in a Web browser for automatic linking the content to a certain Web site.

14 More or less a perceptible watermark in music scores already exists: the copyright information.

15 Asymmetric watermarking schemes have been developed as well, but they have some drawbacks.

16 Blind watermarking schemes are also called public watermarking schemes.

17 These are also called private watermarking schemes.

18 For some media types (e.g., text or music scores), embedding a watermark directly in the content is very difficult. Here, the representation is modified, which effects robustness against conversion and potentially the perceived quality.

19 Sometimes even the term "passive watermarking" is used, which we consider as misleading as no mark is embedded.

20 These secure devices are also called trusted devices, reflecting the assumption that trusts in the security of the systems can be provided.

21 Typically, content servers provide this functionality.

22 Controllers are sometimes also called "DRM controllers."

23 Local storage of the decrypted content depends on the business model. Some business models might allow this. Some might only allow local storage with poor quality (e.g., strongly compressed audio files).

24 Current solutions implement a key cache to increase the systems flexibility. But this also increases the systems vulnerability.

25 Of course the processing power must be sufficient.

26 The MAC address is a unique value associated with a network adapter, and are also known as hardware addresses or physical addresses.

27 At least this is the case nowadays. This might change in the future if the "trusted computing" initiatives succeed. Yet consumers have to pay for this technology and they do not only benefit from it.

28 Other possible consequences, for example, software monopoles, have to be considered carefully, and a thorough observation is necessary to avoid negative effects to economy.

29 Typically, a TV set uses interlacing, which combines two "half"-images into one. DVD players are capable of producing a progressive output signal; one complete frame at once.

30 Due to their motivation "semiprofessional" hackers can be considered as a big threat.

31 Thus, people interested in the protection of their content have to be aware that the higher the monetary benefit is, the bigger is the potential danger that an attacker has commercial interests.

32 Sometimes this kind of hacker is also called crackers.

33 For example, archiving or providing access to visually impaired people are most often allowed by law.

34 Interestingly in the physical world, such a practise is not manageable or allowed. For example, knives are still sold although people can potentially be hurt.

35 There are different opinions on this on other areas, for example, as expressed by Marion and Hacking (1998). For the digital value chain this might be more evident, as content available in digital format can be processed more easily. Thus the cycles are rigorously shorter.

36 This is a general problem especially for digital archives, even without DRM: Will any device to read the content stored on a specific carrier be available in 20 or 30 years?

[37] This, and the resulting architecture, was a direct result of the discussion within the MUSICNETWORK when looking for a possible decentralised solution for unknown musicians.

[38] One example is the success of VHS against Betamax or Video 2000, although VHS was inferior against its competitors.

[39] Although the second and the third scenarios are linked due to the results, the difference is in how rights are established and enforced.

[40] DarkNoiseTechnologies was bought by SunnComm (http://www.sunncomm.com).

This work was previously published in Interactive Multimedia Music Technologies, edited by K. Ng and P. Nesi, pp. 283-324, copyright 2008 by Information Science Reference, formerly known as Idea Group Reference (an imprint of IGI Global).

ABSTRACT

Today, mobile multimedia applications provide customers with only limited means to define what information they wish to receive. However, customers would prefer to receive content that reflects specific personal interests. In this chapter we present a prototype multimedia application that demonstrates personalised content delivery using the multimedia messaging service (MMS) protocol. The development of the application was based on the multimedia middleware framework METIS, which can be easily tailored to specific application needs. The principle application logic was constructed through three indepdent modules, or "plug-ins" that make use of METIS and its underlying event system: the harverster module, which automatically collects multimedia content from configured RSS feeds, the news module, which builds custom content based on user preferences, and the MMS module, which is reponsible for broadcasting the resulting multimedia messages. Our experience with the implementation demonstrated the rapid and modular development made possible by such a flexible middleware framework.

INTRODUCTION

Multimedia messaging service (MMS) has not achieved a similar market acceptance and customer adoption rate as *short message service* (SMS), but is nevertheless one of the primary drivers of new income streams for telecommunication companies and is, in the long run, on the way to becoming a true mass market (Rao & Minakakis, 2003). It provides new opportunities for customised content services and represents a significant advance for innovative mobile applications (Malladi & Agrawal, 2002).

Until now, however, mobile operators have failed to deliver meaningful focused mobile services to their users and customers. Telecommunication companies have made considerable investments (license, implementation costs) into third generation (3G) mobile networks but have not yet generated compensating revenue streams (Vlachos & Vrechopoulos, 2004). Customers are often tired of receiving information from which they get no added value, because the information does not reflect their personal interests and circumstances (Sarker & Wells, 2003). The goal is instead to establish a one-to-one relationship with the user and provide costumers with relevant information only. Through personalisation, the number of messages the customer receives will decrease significantly, thus reducing the number of irrelevant and unwanted messages (Ho & Kwok, 2003).

Currently available MMS subscription services (e.g., Vodafone, 2005) allow customers to define what kind of information they want to receive in a very limited way. Broad categories like *Sports, Business,* or *Headline News* can be defined, but there is no generic mechanism for the selection of more specific concepts within a given domain of interest. The personalised and context-aware services demanded by savvy customers require a mediation layer between the users and content that is capable of modelling complex semantic annotations and relationships, as well as traditional and strongly-typed metadata. These will be defining characteristics of next-generation multimedia middleware.

This paper describes the modular development of a mobile news application, based on a custom multimedia middleware framework. The application supports ontology-driven semantic classification of multimedia content gathered using a widespread news markup language. It allows users to subscribe to content within a particular domain of interest and filters information according to the user's preferences. Moreover it delivers the content via MMS. The example domain of interest is the Soccer World Cup 2006 for which a prototypical ontology for personal news feeds has been developed. However, the middleware framework enables mobile multimedia delivery that is completely independent from the underlying domain-specific ontology.

BACKGROUND AND RELATED WORK

Related Work

At this time, there are no readily available systems that combine the power of ontology-based classification, published syndicated content, and a personalised MMS delivery mechanism. There are however a number of proposals and applications that make use of principles and procedures that are similar to those presented in this chapter.

Closely related to the classification aspect of the presented MMS news application are hierarchical textual classification procedures such as D'Alessio, Murray, Schiaffino, and Kreshenbaum (2000). These approaches mostly consider the categorisation of Web pages and e-mails (see also Sakurai & Suyama, 2005) and classify content according to a fixed classification scheme.

Ontologies that can provide classification in the form of concepts and relationships within a particular domain are used by Patel, Supekar, and Lee

(2003) for similar purposes. The idea behind their work is to use a hierarchical ontology structure in order to suggest the topic of a text. Terms that are extracted from a specific textual representation are mapped on to their corresponding concepts in an ontology. The use of ontologies is one step ahead of the use of general classification schemes as they introduce meaningful semantics between classified items. Similar in this respect is the work of Alani et al. (2003), which attempts to automatically extract ontology-based metadata and build an associated knowledge base from Web pages. The reverse method is also possible as demonstrated by Stuckenschmidt and van Harmelen (2001), who built an ontology from textual analysis instead of classifying the text according to an ontology. Schober, Hermes, and Herzog (2004) go one step further by extending the ontological classification scheme from textual information to images and their associated metadata.

Even more closely related to the topics presented in this paper are the techniques employed in the *news engine Web services* application (News, 2005), which is currently under development. It is based on the news syndication format PRISM and ontological classification, and its goal is to develop news intelligence technology for the semantic Web. This application should enable users to access, select, and personalise the reception of multimedia news content using semantic-based classification and associated inference mechanisms (Fernandez-Garcia & Sanchez-Fernandez, 2004).

News Markup Languages and Standards

News syndication is the process of making content available to a range of news subscribers free of charge or by licensing. This section briefly sketches three current technologies and standards in the field of news syndication: RSS, PRISM, and NewsML.

Our MMS application employs RSS feeds in order to harvest news data, due to the volume and free availability of these types of feeds. Of course this would raise serious copyright issues in a commercial application; however, our approach provides an initial proof of concept, allows the harvesting of significant volumes of data for testing classification algorithms, and is easily upgradeable to a commercially appropriate standard, thanks to the modular nature of the system architecture. For this reason, we describe the RSS standard in more detail than the other more commercially significant standards.

Rich Site Summary (RSS)

First introduced by Netscape in 1999, RSS (which can stand for *RDF site summary*, *rich site summary*, or *really simple syndication* depending on the RSS version) is a group of free lightweight XML-based (quasi) standards that allow users to syndicate, describe and distribute Web site and news content, respectively. Using these formats, content providers distribute headlines and up-to-date content in a brief and structured way. Essentially, RSS describes recent additions to a Web site by making periodical updates. At the same time, consumers use RSS readers and news aggregators to manage and monitor their favourite feeds in one centralised program or location (Hammersley, 2003).

RSS comes in three different flavours: relatively outdated RSS 0.9x, RSS 1.0 and RSS 2.0. RSS 2.0 is currently maintained by the *Berkman Center for Internet and Society* at Harvard. On the other hand RSS 1.0 is a *World Wide Web Consortium* (W3C) standard and was developed independently. Thus RSS 2.0 is not an advancement of RSS 1.0, despite what the version numbers might suggest. The line of RSS development was split into two rival branches that are only marginally compatible. The main difference is that RSS 1.0 is based on the W3C *resource description framework* (RDF) standard, whereas the other

types are not (Wustemann, 2004). In our MMS news application scenario the focus is on RSS 2.0 channels, because of their special characteristics relating to multimedia content and the general availability of feeds of this type in contrast to RSS 1.0.

The top level of an RSS 2.0 document is always a single RSS element, which is followed by a single channel element containing the entire feed's content and its associated metadata. Each channel element incorporates a number of elements providing information on the feed as a whole and furthermore item elements that constitute the actual news and their corresponding message bodies. Items consist of a title element (the headline), a description element (the news text), a link (for further reading), some metadata tags and one or more optional enclosure elements. Enclosures are particularly important in the context of multimedia applications, as they provide external links to additional media files associated with a message item. Enclosures can be images, audio or video files, but also executables or additional text files, and they are used for building up the multimedia base of our MMS news application.

Publishing Requirements for Industry Standard Metadata (PRISM)

Publishing Requirements for Industry Standard Metadata (PRISM, 2004) is a project to build standard XML metadata vocabularies for the publishing industry to facilitate syndicating, aggregating and processing of news, book, magazine and journal content of any type. It provides a framework for the preservation and exchange of content and of its associated metadata through the definition of metadata elements that describe the content in detail.

The impetus behind PRISM is the need for publishers to make effective use of metadata to cut costs from production operations and to increase revenue streams as well as availability for their already produced content through new electronic distribution methods. Metadata in this context makes it possible to automate processes such as content searching, determining rights ownership and personalisation.

News Markup Language (NewsML)

News Markup Language (NewsML) is an open XML-based electronic news standard developed and ratified by the *International Press Telec Council* (IPTC) and lead-managed by the world's largest electronic news provider Reuters (IPTC, 2005). According to Reuters (2005), NewsML could revolutionise publishing, because it allows publishers and journalists to deliver their news and stories to a range of different devices including cell phones, PDAs, and desktop computers. At the same time, it allows content providers to attach rich metadata so that customers only receive the most relevant information according to their preferences.

NewsML is extensible and flexible to suit individual user's needs. The goal is to facilitate the exchange of any kind of news, be it text, photos or other media, accurately and quickly, but it may also be used for news storage and publication of news feeds. This is achieved by bundling the content in a way that allows highly automated processing (NewsML, 2003).

Multimedia Messaging Service and Mobile Network Architecture

Multimedia messaging service (MMS) is an extension to the *short message service* (SMS) protocol, using the *wireless application protocol* (WAP) as enabling technology that allows users to send and receive messages containing any mixture of text, graphics, photographic images, speech and music clips or video sequences. High-speed communication and transmission technologies, such as *general packet radio services* (GPRS) and *universal mobile telecommunications system* (UMTS), provide support for powerful and fast

messaging applications (Sony Ericsson Developers Guidelines, 2004).

MMS Network Architecture

An MMS-enabled mobile device communicates with a WAP gateway using WAP transport protocols over GPRS or UMTS networks.

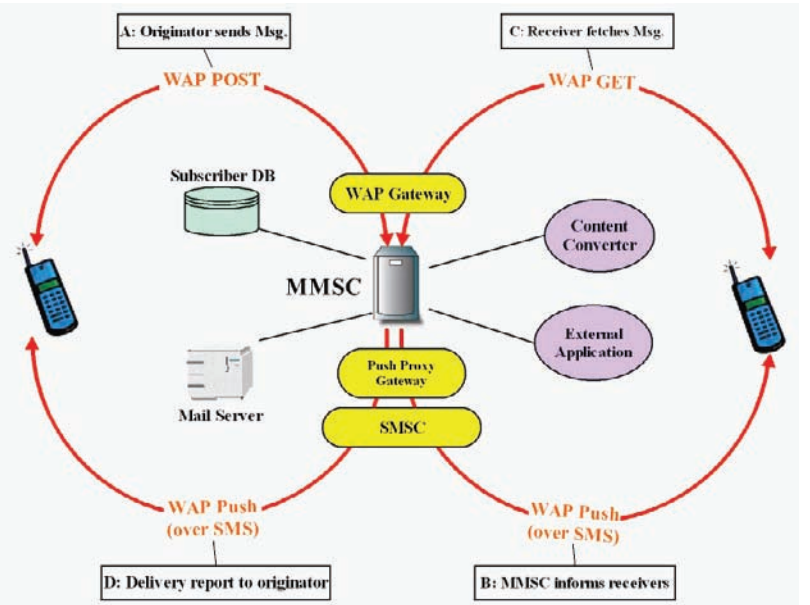
Data is transported between the WAP Gateway and the MMS Centre (MMSC) using the HTTP protocol as indicated in Figure 1. The MMSC is the central and most vital part of the architecture and consists of an MMS Server and an MMS Proxy-Relay. Amongst other functions it stores MMS messages, forwards and routes messages to external networks (external MMSCs), delivers MMS via e-mail (using the SMTP protocol), and performs content adaptation according to the information known about the receiver's mobile phone. This is managed via so-called *user agent profiles* that identify the capabilities of cell phones registered in a provider's network (Sony Ericsson Developers Guidelines, 2004). Leveraging the content-adaption capability of the MMSC is a key feature of our MMS application.

MMS and SMIL

The *Synchronized Multimedia Integration Language* (SMIL) is a simple but powerful XML-based language specified by the W3C that provides mechanisms for the presentation of multimedia objects (Bulterman & Rutledge, 2004). The concept of SMIL as well as MMS presentations in general includes the ordering, layout, sequencing, and timing of multimedia objects as the four important functions of multimedia presentations. Thus a sender of a multimedia message can use SMIL to organise the multimedia content and to define how the multimedia objects are displayed on the receiving device (OMA, 2005).

A subset of SMIL elements must be used (and are used by our application) to determine the presentation format of an MMS message. Listing 1 shows an example SMIL document defining 2 slides (<par> elements), each containing a text,

Figure 1. MMS network architecture (Nokia Technical Report, 2003)



an image, and an audio element, as it would be the case in typical MMS.

MMS Message Structure and WSP Packaging

MMS is implemented on top of WAP 1.2.1 (as of October 2004) and supports messages of up to 100 Kbytes, including header information and payload. In order to transmit an MMS message, all of its parts must be assembled into a multi-part message associated with a corresponding MIME (*multipurpose Internet mail extensions*) type, similar to the manner in which these types are used in other standards such as HTML or SMTP. What is actually sent are so-called MMS *protocol data units* (PDUs). An example of which is shown in Figure 2. In the next step, PDUs are passed into the content section of a *wireless session protocol* (WSP) message, in the case of most mobile networks, or a HTTP message otherwise (Nokia Technical Report, 2003).

One of three possible content type parameters is associated with these content sections, specifying the type of the MMS (Sony Ericsson Developers Guidelines, 2004):

- **Application/vnd.wap.multipart.related:** This type is used if there is a SMIL part present in the MMS. The header must then also include a type parameter application/smil on the first possible position
- **Application/vnd.wap.multipart.mixed:** Used if no SMIL part is included in the MMS
- **Application/vnd.wap.multipart.alternative:** Indicates that the MMS contains alternative content types. The receiving device will choose one supported MIME type from the available ones

The Multimedia Middleware Framework METIS

The following sections give an overview of the METIS multimedia framework, its generic data model, and methods for the extension of its basic functionality by developing semantic modules and

kernel plug-ins. An introduction to the template mechanism that is extensively used in our application is also provided.

System Overview

The METIS framework (King, Popitsch, & Westermann, 2004) provides an infrastructure for the rapid development of multimedia applications. It is essentially a classical middleware application located between highly customisable persistence and visualisation layers. Flexibility was one of the primary design criteria for METIS. As can be seen in Figure 3, this criterion especially applies to the back-end and front-end components of the architecture as well as to the general extensibility through kernel plug-ins and semantic modules. The design as a whole offers a variety of options for the adaptation to specific application needs.

METIS Data Model

The METIS data model provides the basis for complex, typed metadata attributes, hierarchical classification, and content virtualisation. Application developers need only consider their specific data models at the level of ontologies (specified, for example, by RDFS or OWL) which can then be easily mapped to the METIS data model using existing tools. Object relational modelling is handled by the framework and the developer need never concern himself with relational tables or SQL statements.

Figure 3. METIS system architecture

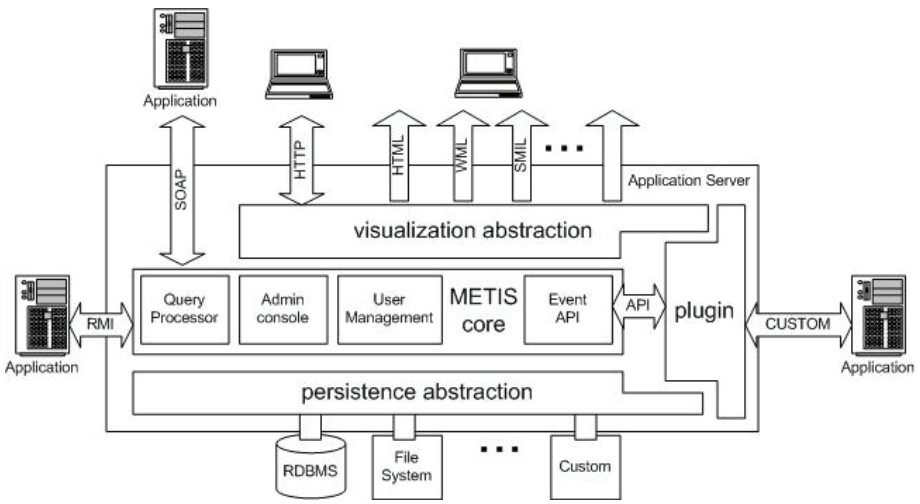

Figure 4. METIS Core Data Model (King et al., 2004)

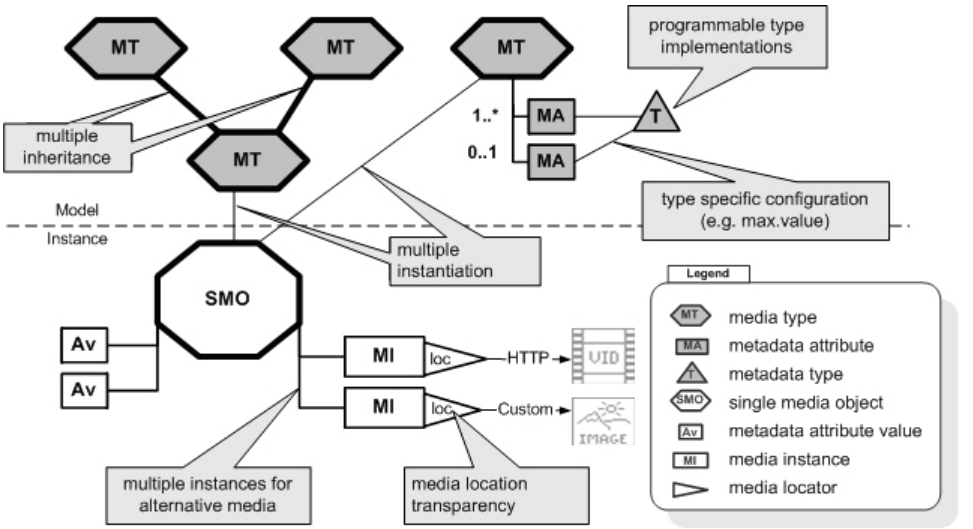

Figure 4 illustrates the basic building blocks of the model and their relationships. Media in METIS are represented as a so-called *single media objects* (SMOs), which are abstract, logical representations of one or more physical media items. Media items are attached to a SMO as *media instances* and connected to the actual media data via *media locaters*, which are in turn a kind of pointer to the data, allowing METIS to address transparently media items in a variety of distributed storage locations such as file systems, databases or Web servers.

As a foundation for semantic classification, media objects can be organised in logical hierarchical categories, known as *media types*. Media types can take part in multiple inheritance as well as multiple instantiation associations. *Metadata attributes* are connected to media types, can be as simple or complex as desired, and can be shared among multiple media types with different cardinalities, default values, and ranges.

Finally, media objects can be connected to each other by binary directed relationships (so-called *associations*). The semantics of these associations are defined by *association types* that are freely configurable within an application domain.

As mentioned previously, there exist simple tools with which domain semantics can be packaged as semantic modules (also called *semantic packs*) that can be dynamically loaded in a given METIS instance and thereby provide the required domain-specific customisations.

Complex Media Objects and Templates

For modelling specific media documents that are made up of several media items, the METIS data model provides *complex media objects* (CMOs). CMOs are quite similar to SMOs when it comes to instantiating media types, taking part in associations and being described by metadata attributes. The crucial difference is that they serve as containers for other media objects, either SMOs or other CMOs. Complex media objects can be rendered in specific visualisation formats by applying the METIS template mechanism (King et al., 2004). A template is an XML representation of a specific multimedia document format (such as SMIL, HTML or SVG), enriched by *placeholders*. When a visualisation of the CMO is requested, these placeholders are dynamically substituted by specific data extracted from the CMO employing

that template, using a format-specific XSLT style sheet. Our MMS application makes use of this template mechanism in order to define the format of MMS messages, by employing the SMIL-based mechanism described in a previous section.

Semantic Modules and Kernel Plugins and the Event Framework

Kernel plug-ins constitute the functional components of an application that extend the basic functionalities provided by the METIS core. These plug-ins not only have access to all customisation frameworks within METIS, but also to the event system, which provides a basic publish/subscribe mechanism. Through the METIS framework, plug-ins can subscribe to certain predefined METIS events and can easily implement their own new application-specific events. This loose coupling between functional extensions provided by the event framework allows large modular applications to be implemented with METIS.

THE MMS NEWS APPLICATION

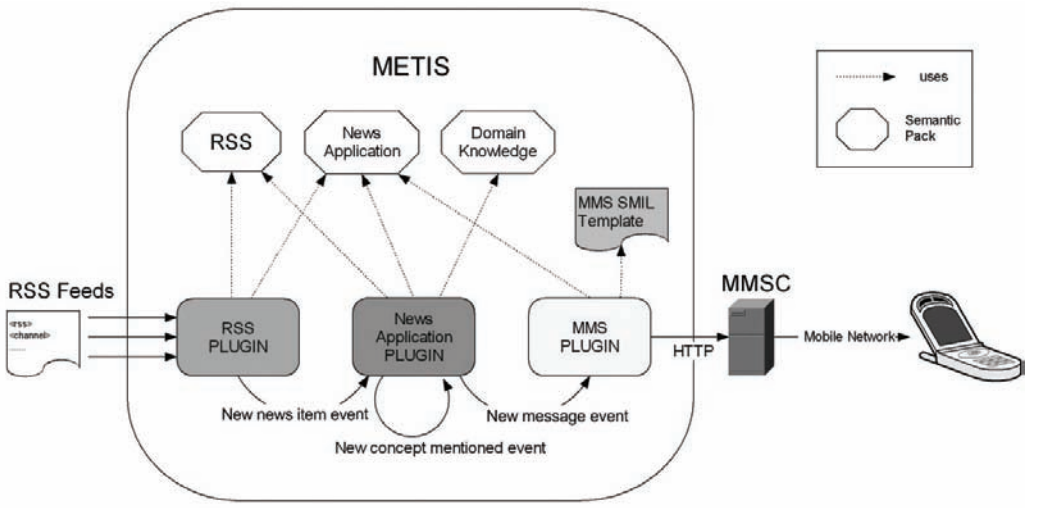
The METIS framework is used extensively to implement our modular application for content delivery in mobile networks. This *MMS news application* illustrates two strengths of METIS: extensibility and fast implementation time.

In order to demonstrate these advantages and the core functionalities, the prototype news application implements a showcase in the wider area of the Soccer World Cup 2006 in Germany. We present an ontology for this domain, which allows a relatively confined set of topics and their relationships to be modelled. However, the system is designed to be as open and extensible as possible and allows mobile multimedia content delivery that is completely independent from the underlying domain-specific ontology.

System Architecture

An overview of principal components of the *MMS news application*'s modular architecture is given in Figure 5. The implementation is split into three functional parts: the RSS import module, the news application module (containing the main applica-

Figure 5. MMS news application architecture (simplified)



tion logic), and the MMS output and transmission module. Each module is implemented as a kernel plug-in, and each module is loosely connected with other plug-ins through the METIS event mechanism.

This approach makes it possible to cleanly separate functionalities into logical modules. It is therefore simple to integrate various functional units into the application's context and substitute existing plug-ins with newly implemented ones whenever changes in the application's environment are required. The interface to which all these plug-ins must adhere is defined by the various events that are issued by components that adopt a given role in the application.

From a high-level perspective, the RSS plug-in takes the role of the multimedia content source that loads multimedia news items into the system. Obviously, RSS would not be the choice for a commercial application; the previously mentioned NewsML and PRISM standards, whose feeds are not normally free of charge, would be more powerful alternatives.

RSS was chosen for the prototype as it allows the demonstration of the essential strengths and advantages of the presented approach with no associated costs. Furthermore it is easy to implement and allows the testing of the whole application on large datasets. In the future, additional multimedia content source plug-ins based on NewsML or PRISM could be quickly developed to replace the RSS plug-in.

The *NewsApplication* plug-in is the core module of the whole application. It integrates the surrounding plug-ins and uses their provided functionalities to create personalised news content. This plug-in itself offers flexibility in the mechanisms used to find topics mentioned in news items as well as in the creation of messages for specific users.

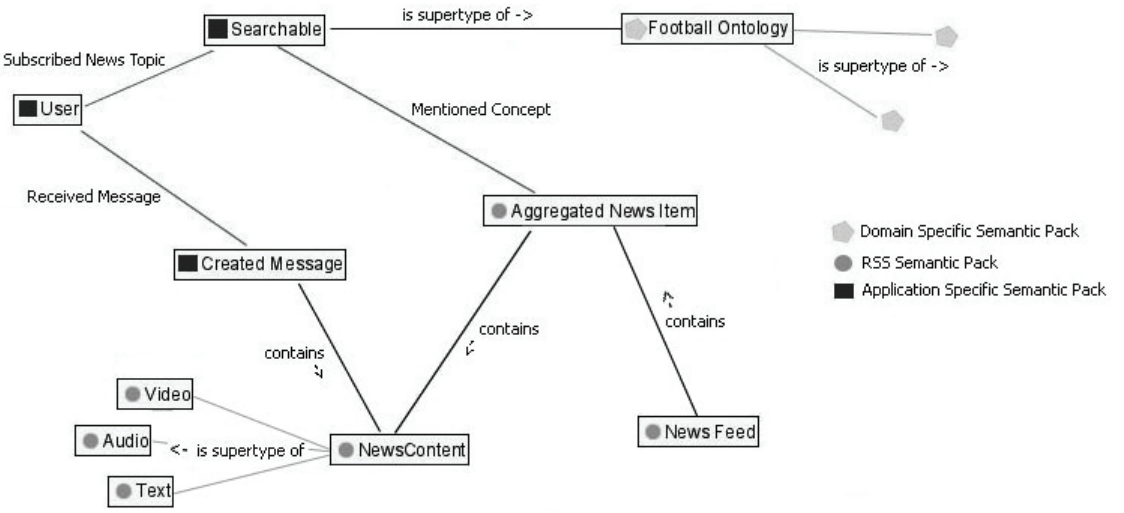
The MMS plug-in fulfils the role of the content delivery mechanism within the *MMS news application* by linking the application to mobile network environments. In the current prototype it is used to send MMS messages via an associated MMSC to a user's mobile handset. Once again, the MMS plug-in offers a variety of extension possibilities and is very flexible when it comes to the system used for the actual MMS transmission. It could be easily substituted by other content delivery plug-ins that target different receiving environments and devices. For example, one might consider a SMS delivery mechanism or a mechanism that delivers aggregated news feeds about certain topics to Web-based news reader applications.

Data Model

The data model and domain-specific semantics of a METIS-based application must be specified through the *semantic pack* mechanism. Semantic packs are to a large extent quite similar to ontologies that define the semantics of specific domains of knowledge by modelling classes, attributes, and relationships. The *MMS news application* is based on three independent semantic packs:

- **RSS semantic pack:** This module maps the RSS 2.0 element and attribute sets to the METIS environment, and supports import from previous RSS versions including RSS 1.0 (without additional modules). Media types included are *news feed*, *aggregated news item*, *news content* with corresponding attributes (e.g., *title*, *description* or *publication date*) as well as general purpose media types such as *image*, *text*, *audio*, and *video* that are all child elements of *news content*. Associations between these elements are defined as well. Generally, this semantic pack is intended to be as independent as possible from the underlying publishing standard that is used, and as extensible as possible in order to facilitate the implementation of other types of import plug-ins
- **News application semantic pack:** This module provides the application-specific

Figure 6. MMS news application semantic pack dependencies



management ontology. It defines media types and metadata attributes that are required by the internal logic of the application in order to store and differentiate between application-specific media objects. Media types in this category are *user, created message,* and *searchable*. A *User* normally subscribes to multiple *searchable* media object instances (SMOs) that are supplied by the domain-specific semantic pack, and associations of type *subscribed news topic* are created between these. Furthermore, associations of type *received message* are instantiated between a *user* and all the *created messages* he has received as a result of his subscriptions

- **Domain-specific semantic pack:** This module constitutes the domain-specific component of the application used for the subscription services and the applied ontology-based classification method. The application's internal logic is completely independent of the domain of interest that is defined by this semantic pack. As a demonstrator, an ontology for soccer was implemented, but additional domains can be implemented and plugged into the existing application with minimal effort

The general dependencies between the three semantic packs and the specific media and association types are presented in Figure 6.

Domain-Specific Semantics and Knowledge Base

The domain-specific semantic pack contains key concepts and their relationships within a specific domain of interest, and defines the structure of a knowledge base containing specific instances of defined classes that must be instantiated. The *MMS news application* is independent of the domain of interest supplied by this semantic pack; any ontology satisfying the basic requirement of having a single parent class from which all other classes are directly or indirectly derived can be loaded into the system and used as a basis for the subscription mechanism.

Domain concepts or classes are stored in the METIS environment as media types. A concept instance is modelled as a SMO of the corresponding concept's media type. In our prototype, all classes are direct or indirect subclasses of the abstract base class *Football Ontology.* Example classes (media types) are *Field Player, Trainer,*

National Team, *Club*, and *Referee*. Furthermore, an application-specific media type *searchable* is included, which provides the required *search term* metadata attribute. This search term enables the textual identification of the instance through the presently simple algorithm based on matching regular-expressions. Domain associations form the basis for the semantic classification algorithm as they relate concepts (i.e. classes) and establish meaningful relationships between them.

Instances (e.g., *David Beckham*) of concepts (e.g., *Field Player*) can be included within the semantic pack itself or defined via the *news application's* user interface. The only constraint that instances within an imported ontology must satisfy is that they must supply at least one identifying search term string attribute for the ontology-based classification mechanism.

Every instance added to the system becomes visible to end-users, who can then subscribe to specific concept instances and receive MMS messages associated with them.

In the case of our prototype, a knowledge base of about 250 instances and their associations was developed in approximately 4 hours. This suggests that it is possible to implement other domains of interest and to adapt the whole application to other application scenarios in a reasonably short time.

Module Integration and Event Mechanism

The RSS plug-in provides all RSS-related mechanisms. RSS news feeds typically contain news items that contain the actual messages. Whenever an item is added and stored, the RSS plug-in informs all interested system components of this fact via a *new news item event*. The only subscriber to this event in the current architecture is the news application plug-in, which is subsequently activated. It searches the new news item for occurrences of domain-specific concept instances (e.g., the instance *David Beckham*) contained in the domain-specific knowledge base. Whenever such an occurrence is found, a *new concept mentioned event* is issued. The news application then attempts to find subscribers to the discovered concept instance (i.e., users who want to receive messages about it) as well as subscribers of associated instances. Associated concept instances in this respect mean instances that are directly connected to the discovered concept through a relationship in the domain-specific ontology. If a user has chosen to receive messages from related instances (by default, a user would receive messages only directly related to the subscribed concept), he will also be added to the set of found users. As an example, consider a subscriber of the instance *English national team* who also chooses to receive messages from related concept instances; he would, for example, also receive messages about *David Beckham*, because *Beckham* is a member of that team. In this case, the user would be an *indirect subscriber* to the Beckham concept instance.

Whenever direct or indirect subscribers are found, the plug-in creates a new CMO (of type *created message*) containing various SMOs such as a news text, suitable images, video or audio items. It is important to note that this newly created message is not a one-to-one translation of the news item contained in the RSS feed. The news application searches the multimedia document base and tries to find media instances that are associated with the discovered concept instance and may be suitable for the newly created message.

The architecture is designed to be as open and extensible as possible. Implementations of new algorithms for ontology-based classification and the associated message-creation mechanism can be easily upgraded within in the application.

Having assembled this message, a *new message event* is issued and the MMS plug-in, as a subscriber to this event, sends the message as a MMS to the users' mobile phones. Outgoing messages are formatted using the METIS template mechanism in conjunction with a predefined MMS

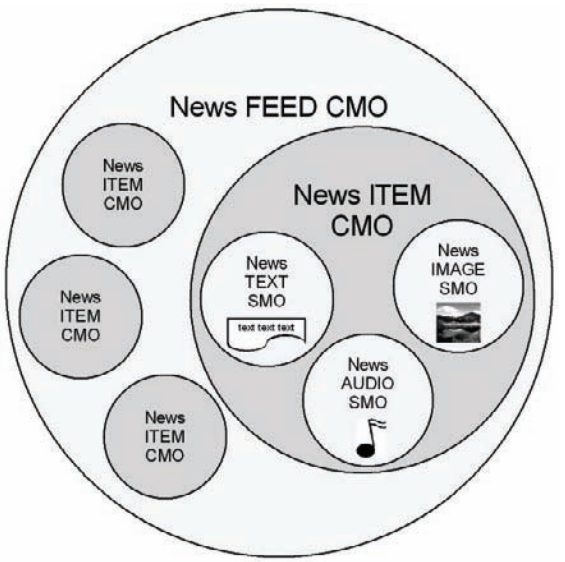
SMIL template. The application could be easily extended to allow users to choose from a variety of templates and define the final format of their received messages.

RSS Import

The RSS import plug-in fulfils the role of an RSS input parser and news aggregator that manages multiple RSS feeds simultaneously and makes their content available to the other components of the application.

Using media types and attributes specified in the RSS semantic pack, the RSS plug-in maps feeds to corresponding METIS media objects by parsing these and extracting media and metadata. In general, a feed is represented as a METIS CMO as depicted in Figure 7. The *FEED CMO* (type: *news feed*) can incorporate several *News ITEM CMOs* (type *aggregated news item*), which in turn include multiple *media SMOs* (subtypes of *news content*) that map RSS media enclosures included in the feed.

Figure 7. News FEED complex media object containing CMOs and SMOs



By regularly searching and updating the stored feeds, a multimedia document base is gradually constructed over time.

The RSS plug-in also functions as a common RSS newsreader and aggregator by providing an HTML visualisation of the created *News FEED* CMO. This again demonstrates the power and adaptability of the METIS approach, as the RSS plug-in can already serve as a standalone application without including it the context of the *MMS news application.*

Ontology-Driven Message Creation

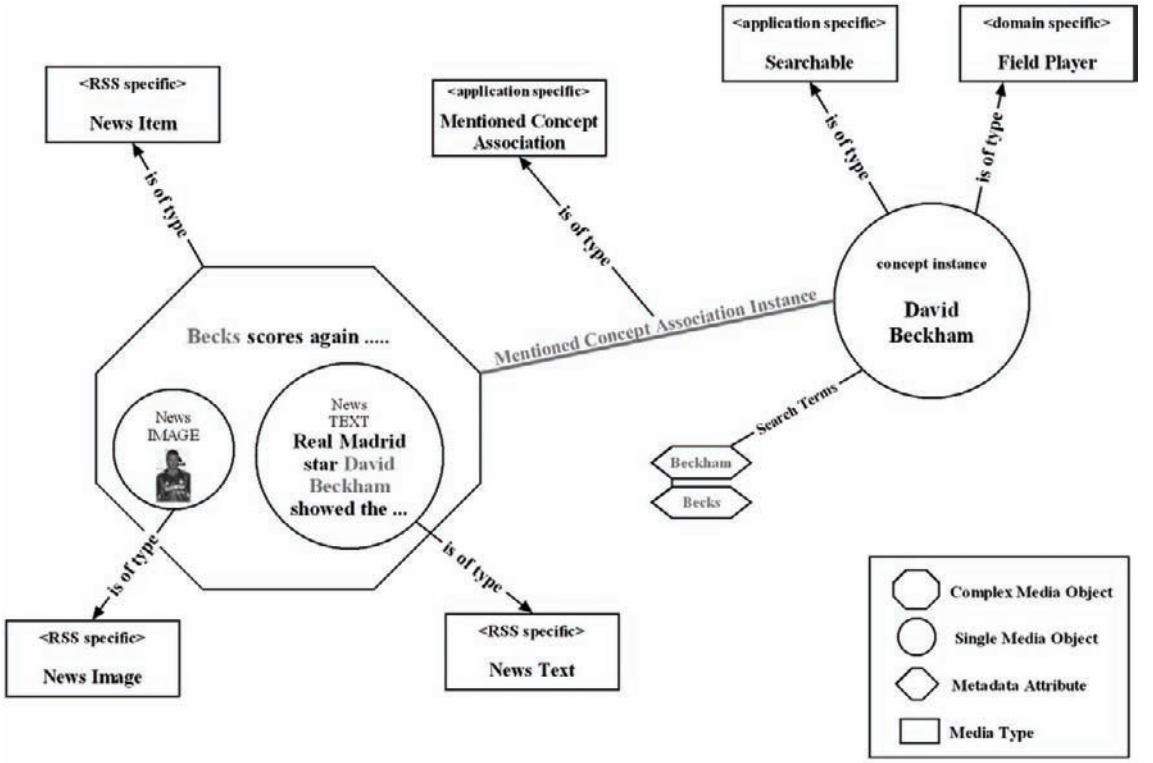
The *news application* plug-in provides core functionalities in the areas of ontology-based classification and discovery of specific media objects, as well as message creation from these search results.

The search terms provided by the knowledge base are used to identify textual occurrences of concept instances in *news ITEM CMOs.* We make the simplifying assumption that all other *media SMOs* included in this *news ITEM CMO* are also related to the discovered instance.

The news application plug-in uses this classification mechanism to relate concept instances to news items and their included media objects. A simple strategy based on regular expressions that searches all *news TEXT SMOs* for the occurrences of concept instance search terms defined in the knowledge base is currently implemented. This approach allows us to easily test the whole modular application on large datasets. Different search strategies can be utilised in this context and new ones can be added easily. For example, advanced full text analysis approaches could be employed in the application; this is a subject for our future research.

When a search term is found, a METIS association (of type *Mentioned Concept*) between the news text's *news ITEM CMO* and the concept instance SMO in the knowledge base is created, as depicted in Figure 8. This in turn fires a *new*

Figure 8. Concept mentioned association example



mentioned concept event that triggers the message creation mechanism.

Created messages are stored in a new container CMO of type *created message*. In most cases, news items contain only textual headlines; information and suitable media objects must be added in order to create a multimedia message for MMS delivery.

Once again, the domain-specific ontology provides valuable information about the relationships between a specific concept instance and other instances. As instances are bound to news items, the relationships can be derived for these news items as well. Media SMOs can thus be harvested from concept instances not bound to them, but bound to a closely related instance. Consider an example in which there are no images of the instance *David Beckham* available — in this case an image could be taken from an instance of *English National Team* as the latter is related to the former via an association of type *team member*. Only directly related concepts are taken into account, because we assume that the further apart two instances are, the more likely it is that unsuitable *media SMOs* will be chosen.

MMS Creation and Content Delivery

The purpose of the MMS plug-in is to assemble a MMS message from a message CMO (of type *created message*) and transmit it to subscribed users. This plug-in employs the METIS template mechanism to create suitable SMIL-based MMS slideshow presentations, including media objects supplied by the *created message*. The template includes placeholders that are dynamically replaced by the actual multimedia object instance data.

During the next step, the MMS message is packaged as a binary stream (because the MMS format does not allow any links to external media)

consisting of the actual media data referenced by the included SMOs and the generated SMIL file. General message attributes such as the receiver's phone number, the MMS title and subject, as supplied by the *created message* CMO, are also included in the header. That package is then sent to a MMSC, which continues by sending the MMS to the corresponding mobile device over a carrier's network.

This architecture has some specific advantages over other methods of sending MMS messages. First of all, the MMSC usually offers a mechanism for content adaptation and conversion according to a mobile phone's capabilities. This frees the METIS MMS plug-in from any consideration of the supplied media items in terms of conversion and adaptation to specific mobile devices. The second reason is that this design makes it possible to switch between MMSC implementations quite easily. Thus it is possible to adapt the *MMS news application* to any provider's or carrier's network architecture with a minimum amount of effort. Live environments that can send thousands of messages per second, compared to 2-4 messages in the testing environment, are therefore a future possibility.

CONCLUSION AND FUTURE WORK

Today, mobile multimedia applications provide customers with only limited means to define what kind of information they want to receive. Customers would prefer to receive information that reflects their specific personal interests, and this requires a mediation layer between the users and content that is capable of modelling complex semantic annotations and relationships. This will be a crucial characteristic of next-generation multimedia platforms.

In this chapter we have presented a prototype multimedia application that demonstrates this type of personalised content delivery. The development of the application was based on a custom multimedia middleware framework, METIS, which can be easily tailored to specific application needs. Our experience with the implementation demonstrated the rapid and modular development made possible by such a flexible middleware framework.

The example domain chosen to illustrate our approach is the Soccer World Cup. An ontology for personal news feeds from this domain was developed, and our experience indicates that similar ontologies and the corresponding knowledge bases for other domains can be created with very little effort. In any case, the application architecture is independent of the specific application domain.

The first module of our prototype application harvests media information from RSS feeds. As a result of the modular application architecture, one could easily integrate additional content sources (for example, encoded in NewsML) that are commercially available from many news agencies, in order to create a commercial application.

In the second module, harvested news items are classified according to the concepts given by the ontology. In our demonstrator application we employed simple text classification techniques, but again thanks to flexible system architecture, more advanced classification techniques can be developed without altering other system components. Future work will focus on more advanced methods of content classfication and on measuring the quality of aggregated media content.

In the final application module, multimedia news messages are composed and delivered to users, according to preferences specified during the subscription process. In the demonstrator we composed and delivered SMIL-based MMS messages to the mobile phones of registered users using a local MMSC. However, the integration with commercial MMSCs, enabling mass transmission of MMS messages, would require no additional implementation and minimal configuration effort.

In conclusion, we believe that the guiding principles for future mobile multimedia applications must be derived from personalised services

(i.e., "personalised content is king.") Through personalisation, such applications can provide the possibility for mobile service providers to improve customer retention and usage patterns through the created added value for the customer.

KEY TERMS

3G Mobile: Third generation mobile network, such as UMTS in Europe or CDMA2000 in the U.S. and Japan.

METIS: METIS is an intermedia middleware solution facilitating the exchange of data between diverse applications as well as the integration of diverse data sources, demantic searching and content adaptation for display on various publishing platforms.

MMS: Multimedia Messaging Service is a system used to transmit various kinds of multimedia messages and presentations over mobile networks.

NewsML: News Markup Language is an open XML-based electronic news standard used by major news providers to exchange news and stories and to facilitate the delivery of these to diverse receiving devices.

News Syndication: Is the process of making content available to a range of news subscribers free of charge or by licensing.

Ontology: A conceptual schema representing the knowledge of a certain domain of interest.

PRISM: Publishing Requirements for Industry Standard Metadata is a standard XML metadata volabulary for the publishing industry to facilitate syndicating, aggregating, and processing of content of any type.

Semantic Classification: Is the classification of multimedia objects and concepts and their interrelationships using semantic information provided by a domain schema (i.e., ontology).

SMIL: Synchronized Multimedia Integration Language is a XML-based language for integrating sets of multimedia objects into a multimedia presentation.

RSS: Really Simple Syndication (also Rich Site Summary and RDF Site Summary) is a XML-based syndication language that allows users to subscribe to news services provided by Web sites and Weblogs.

ABSTRACT

Advances in technology have enabled a proliferation of mobile devices and a broad spectrum of novel and out breaking solutions for new applications and services. In the present, more and more people and companies are demanding mobile access to multimedia services such as real-time rich media. Today, it is necessary to be able to predict adaptation behaviour which concerns and addresses not only the mobile usage or the infrastructure availability, but the service quality especially the continuity of service. Our chapter provides insight to new challenges of mobile multimedia services and applications: Wifi indoor positioning system adapted to heterogeneous building, static and learning mobility prediction, predictive handover policy for multimedia cache management, mobile multimedia guide (such as museum), and network scalability.

INTRODUCTION

The rapid deployment and growth of multimedia applications are increasing with the appearance

of new mobile services and new usages. Nowadays, taking advantage of the arrival of large bandwidth of wireless networks, it is becoming more feasible to stream numerous rich media flows towards mobile and terminal devices. However, some bottlenecks subsist when addressing, firstly, the heterogeneity of Wifi covered territories and secondly the intrinsic rich media constraints. We compare mobility to, first of all, a continuous move within a geographical space, and second a discrete space on a logical scale of the diffusion's network (from access point to access point).

This chapter deals with applications handling large size and continuous rich media communication (i.e., audio or video media). Continuous media require the installation of a specific infrastructure of diffusion guaranteeing the delivery periods. We are interested in mobiles implemented within a space provided with multiple access points, with a more or less homogeneous space cover. In such context, it is important the infrastructure reacts rapidly, or use preventive measures during the changes of access point.

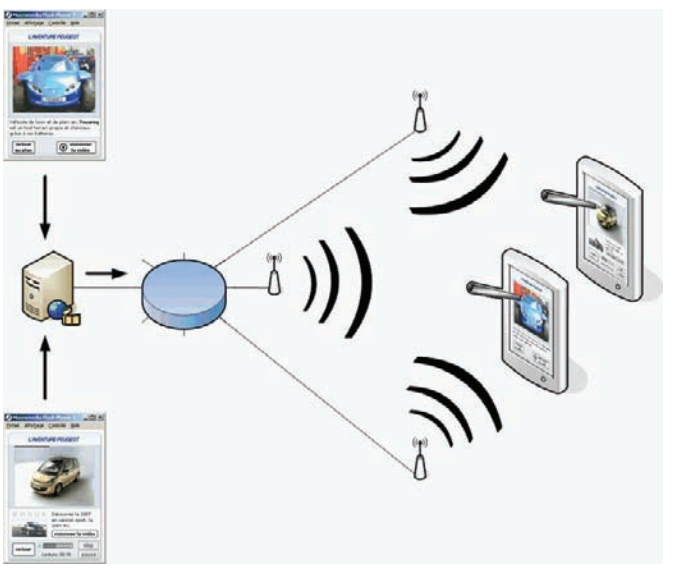
In this chapter, we do not consider the dynamic flow adaptation but rather, we consider already optimized flows dedicated to mobile devices. Thus, whatever the device nature is (pda, tablet pc, etc.), we assume there is a suitable flow adapted to each target. The reader interested in flow adaptation may refer to (Bourgeois, Mory, & Spies, 2003).

To illustrate our purpose, we use GUINUMO, a mobile numerical guide. Such guide demonstrates the accuracy and pertinence of retrieving and making use of both the visual or audio information, and the localization of the pervasive device, during the time-visit of scenarized museums. Within this framework, the media are suited to fit the specific device.

In the sequel, first of all we present the techniques of localization of the devices connected by hertzian way. We further investigate the trilateration technique and evaluate the efficiency of various methods according to several conditions of implementation.

In order to set up a preventive treatment of mobility we show that it is necessary to determine, at least statistically, the future position of a mobile. Then, we describe the methods allowing predicting, in the short run, the position of a mobile. We detail how, thanks to methods of training, it is possible to refine this prediction.

Figure 1. Synthetic schema of GUINUMO's platform



In the second part of this chapter, we introduce the concept of cache, as a necessary element in the chain of continuous media diffusion. Caches make it possible to ensure the continuity and the extensibility of the diffusion's infrastructure. We start off by describing the standard methods of managements and co-operation of the caches for continuous media. We proceed by explaining the mechanisms required to manage the change of access point: *handoff*. Then we detail how preventive methods allow optimizing the continuity of flows diffusion. We also present how to integrate these mechanisms in a platform of diffusion and reception (GUINUMO). We describe use-cases of this device. Finally, we conclude with future trends about preventive treatment of mobility. We specify how the coming standards will allow optimizing the handoff and positioning determination mechanisms.

CONSIDERING MOBILITY

Positioning

Positioning is required to provide location-related services. By positioning we mean determining a mobile's geographical coordinates.

Major Positioning Techniques

Global positioning system (GPS). The GPS (Alouini, 1996) is the system allowing locating an apparatus on the surface of the planet or in the atmosphere, using reference satellites whose positions are known. This system has been essential for several years. Thanks to preliminary synchronization of the satellites with the GPS receiver, the latter can compute, based on the time of course between the satellites and the receiver, the distance separating it from each satellite. Trilateration (Fang, 1986) means the intersection of the spheres determined by the distances between the mobile device and each satellite and the receiver's position is calculated. The precision is about ±5 meters for civil applications. The main drawback is that it does not function well enough indoors, in city centres, or in raised or leafy environments.

GSM terminal positioning, standing for global system for mobile communication (GSM), is the main mobile telephony standard in use. This standard has given birth to three positioning methods. For each method, setup and accuracy vary. The methods are the *positioning by cell*, the *computation of the distance according to the signal strength,* and the *distance computation by time difference.*

The positioning by cell is basic. Interrogating the BTS (base transmitting station) is sufficient to identify to which one the mobile is connected. The mobile phone is located in the cover area of the said BTS. This method has a variable accuracy, from 100 meters to several miles (depending on the cell size, itself depending on the mobile phones density). In cases where a service like calling the mobile phone is provided, such accuracy is enough.

The positioning by measuring the signal strength is simple too. Knowing the radio wave weakening according to the distance between the transmitter and the receiver, the distances towards the BTS can be extrapolated by measuring the signal strength. With the distances towards the BTS (which positions are known), the trilateration, exposed in the paragraph concerning GPS, gives the position of the mobile phone. The accuracy obtained is between 50 and 500 meters.

Enhanced observed time difference (EOTD) is a method to estimate the time for the signal to go from the mobile phone to the BTS. This technique is usually employed to adapt the transmission timing of the mobile phones according to their distance to the BTS, thus allowing the scheduling of the packets in the time slots. Without this method, the packets would come to collision near the BTS. The adaptation of the transmission timing is called Timing Advance and requires

the synchronization of the BTS and the mobile phones. The distance computation with the time difference is based on EOTD to compute the distance between the BTS and the mobile phone. Knowing the time used by the signal to go from the mobile to the BTS and the wave speed, we can compute the distance. Then, trilateration gives the position of the mobile phone.

Wifi positioning techniques can be classified into two main categories, the one based on signal *strength cartography*, and the other which determines a relation between signal strength and distance. That makes the location computation possible using trilateration.

Within the RADAR system (Bahl & Padmanabhan, 2000), the mobile terminal positioning uses a signal strength map of the covered area. The geographic coordinates, the signal strength measurements and the mobile orientation are stored in a database. The signal strength map can either be constituted by computation or by physical measurements. The signal strength measurement from each access point is compared with the reference points stored in the database. The cartography-based positioning technique has a 2-to-3-meter precision.

Wang, Jia, and Lee (2003) present a *positioning technique based on a radio wave propagation model*. This model aims at expressing the mathematical relation between the distance from transmitter to receiver and the signal strength. The mathematical expression is obtained by polynomial regression of the third degree. The advantage of this technique is the speed of positioning. However, there is a main drawback. A lot of data are required for the regression to be accurate, which involves a high cost in measurement time. On top of that, it is possible to be confronted with singularities in the buildings where the positioning technique is implemented.

The white paper of Interlink Networks (2002) deals with security issues. Its first objective is to locate rogue mobile terminals and access points which try to infiltrate a network through its wireless part. The authors take signal strength measurements at many locations of many buildings. The results of these measurements are used to establish a radio wave propagation model. This model is based on the Friis relation. The Friis relation expresses the signal strength in function of distance, in a free space environment. The Friis-based model is adapted to fit the conditions of implementation. The precision observed is close to 2 meters. The main advantage of this technique is its setup speed. However, some singular geographic points were observed where the precision was worse than 8 meters. The main drawback of this technique is the unique exponent used in the Friis equation.

The best precision is obtained by the signal strength cartography-based technique. However, it uses lots of resources and computing time to use a signal strength map. A long setup time is also required, and it has no reactivity when topological changes occur. These drawbacks partially affect the polynomial regression-based technique because of the need for data in order to obtain the polynomial expression of the distance. Although its precision is less accurate than that of the previous technique, the technique based on an alternative to the Friis equation is very quick to setup and use. Thus, it is well adapted to topological changes.

Singular points are intrinsic to the topological heterogeneity. Buildings are composed of obstacles which interfere with radio wave propagation. The obstacles can be of various natures (Larnon, 1998) and their layout can be irregular. When facing such unfavourable cases, the signal strength cartography shows better results because it fits the building, whereas the propagation model-based techniques consider the topology uniformly.

GeoMovie

The Interlink Networks (2002) approach is chosen to implement our positioning system. It has indeed the advantages of speed and simplicity. It

is interesting with mobile terminals which have little computation power. In Lassabe, Baala, Canalda, Chatonnay, and Spies (2005), we explain the drawbacks of a uniform computation in order to determine the distance according to the signal strength. We first describe the common sources of radio wave distortion and their predominance within a heterogeneous environment. Second, we highlight the radio wave distortion indoor environments with the help of our experiments and we test the model of Interlink Networks, to reveal its limits in a heterogeneous environment.

The Friis equation:

$$\frac{P_R}{P_T} = G_R G_T (\frac{\lambda}{4\pi d})^2$$

where P_R and P_T are respectively the power available at the receiving antenna and the power supplied to the source antenna;

- G_R and G_T are respectively the receiver antenna gain and the transmitter antenna gain
- λ is the carrier wavelength
- d is the transmitter-receiver distance

The Friis equation expresses the signal strength loss in function of the distance *d*. The radio wave absorption by obstacles is similar to the free-space loss but it is generally greater.

We use a reciprocal expression to the Friis equation to determine a value replacing the square of the distance adapted to the environment where the positioning will be achieved. Sample measurements are used to compute the value adapted, which is different for each access point. Then, we use the expression of the distance according to the signal strength, taking into account the new coefficient in the such-modified Friis equation. Trilateration for itself is achieved by an algorithm trying to minimize the distance between the circles centred on the access points and whose radius are the distances towards the mobile terminal (see Figure 2).

The radio waves are affected by the presence of topological components altering the radio waves trajectory and therefore modify the signal strength. The phenomenon we are more likely to observe is wave reflection. The most common sources of wave trajectory distortion are metal equipment that induces huge signal reflections, preventing it from reaching areas theoretically within range. Devices functioning at frequencies close to Wifi frequencies also distort the signal by covering it with great noise.

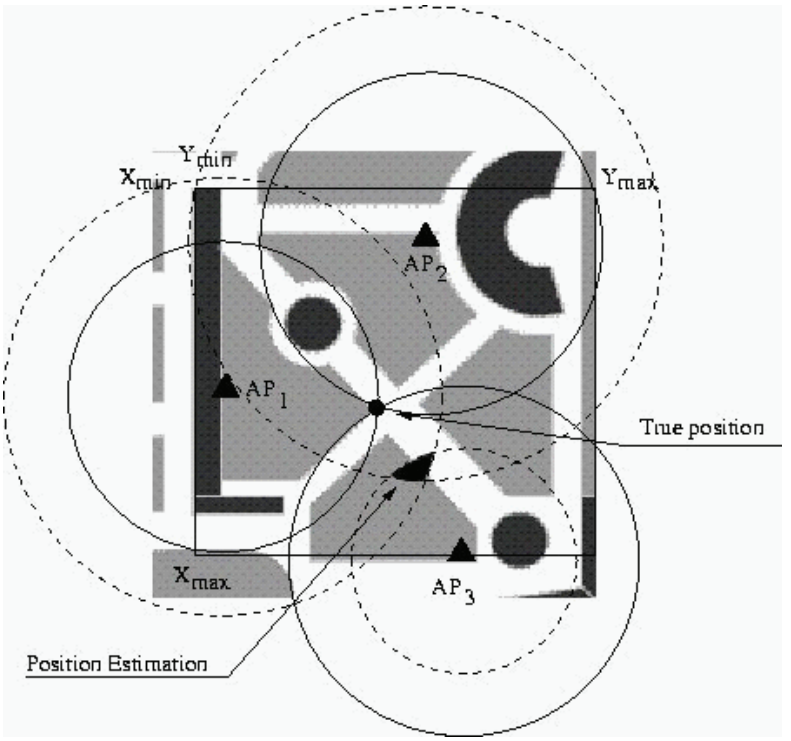
Predictive Positioning

Knowing a mobile terminal position is not sufficient to ensure service continuity. Mobility prediction is required to do so. Predicting the mobile terminal movements requires modelling the trajectories of the mobile terminals. We present two mobility models. The first one models the *trajectories by the movement vectors* of the mobile terminals. It is a static method in which a simple trajectory equation is used. The second one is based on the *learning of the mobile terminal movements*. It is a dynamic method which can be updated when the users change their movements habits. In particular, we present the hidden Markov model (HMM) (Rabiner, 1989). These learning models can be extended by taking into account some mobility patterns.

Trajectory Calculation

In a project to increase routing efficiency in *ad hoc* networks (Lee, Su, & Gerla, 2000), mobility prediction is used. A mobile terminal trajectory at a given time is modelled by the direction and the coordinates of the speed vector of the mobile terminal trajectory. These data are sufficient to anticipate the future position of a mobile terminal. They also allow estimating the remaining connection time between two mobile terminals.

Figure 2. Geolocation based on trilateration technic



Simulations based on this model show a growth of the routing efficiency. However, the experiment hypotheses are not always realized in real conditions. The hypotheses are a positioning of the mobile terminal without error and the uniformity of its trajectory. If the mobile terminal follows a complex course, the routing loses its efficiency.

Learning from the Movements

Another mobility management method is based on the learning of the mobile terminal movements. The learning can be based on several models such as Markov model or automata. Learning the moves allow to compute transition probabilities from state to state. It is interesting because the states can be physical areas or logical states such as the dependency from a multimedia cache or the connection to a base station (in GSM, or access point in Wifi).

Use of Hidden Markov Model

In the article from the University of Liège (François, Leduc, & Martin, 2003), a mobility prediction model for mobile networks is presented. It is based on the hidden Markov model. The transition probabilities between the states are determined by a learning system. During the learning, the mobile terminals regularly send their position to the base stations. The base stations save the transitions from a state to another and compute the transition probabilities.

Simulations without positioning errors are used. The model accuracy is sufficient to predict the mobile terminal next movements. In further work (François, Leduc, & Martin, 2004), an error is added to the mobile terminal positioning. The results are less accurate but still good. When using the first two results, the prediction is 75% right with a 15% noise on the signal strength and

five observations to compute the next state. These conditions are the worst tested.

Mobility Patterns

Mobility patterns are built from logs of several visits. They are used to identify classes of equivalence. Based on such identified classes of equivalence, it is possible to characterise some visitors' behaviour by attaching to visitors (Chardonnel & Van Der Knaap, 2002), and during their visit, the classes matched with behaviour logs, for example. Then, when a user is attached to one (or more) classe(s), it becomes easier to be accurate when predicting where they are going to be located and which media he is going to ask for.

Mobility patterns matching is made on the fly during visits. Thus, as the behaviour of a visitor may change during their visit, class matching must provide a mechanism for identifying new behaviour and adapt any predictions which concern either the next geolocation, or the next interaction with the mobile terminal, or else solicitation of new media. Mobility patterns are build wether online or offline, using the log file of the system.

STREAMING FOR MANY MOBILE USERS

We have seen, in the previous section, that it is possible to locate a mobile terminal in the physical space. It is achieved with accuracy depending on several criteria. The knowledge of the position also involves a possibility to predict the close future moves of the mobile terminal. The best methods are actually based on movements learning. Both the positioning and the mobility prediction allow the service continuity.

Streaming video to many mobile users brings problems which may be categorized in two classes. Firstly, the huge amount of data which has to be sent, blocks the network and the servers, and decreases the interactivity. And secondly, the tight real time requirements of video streaming cannot cope with the latency induced by the distance of clients moving away from the source.

The first class of problems may be solved by using a cache (Cao & Irani, 1997). A cache may be seen as an empty server at time 0. It may transmit the objects it possesses, like a server. Its particularity resides in the fact that it may request objects from other servers or caches and store them temporarily to serve them later. Caches are placed near the clients to reduce the length of the paths and therefore enhance the interactivity and avoid bottlenecks. Moreover, to cover wide areas and serve many users, several caches may cooperate in a set of distributed and cooperating caches.

Caches are managed by several policies: the role of the insertion policy is to decide when and which new documents should be stored on the cache, the removal policy is dedicated to the cleaning of the storage space, the admission policy considers if we can accept a new client, and the aim of the sibling (or cooperation) policy is to take care of the content of the neighbouring caches in a distributed system. Many examples of such policies may be found in the literature (Balamash & Krunz, 2004), some of them are dedicated to specific content such as video (Podlipnig & Boszormenyi, 2002; Rejaie & Kangasharju, 2001). However, none of these policies cope with the problems related to the mobility of the clients.

Mobility in Video Caches

Taking into account the mobility of the users brings new constraints to the field of caches. These not only store and serve the data according to the requests they receive any more, but they must also manage the mobility of the clients. Indeed, the usual operation of the caches is based on the observation of the requests they receive. In a traditional scheme, the topology of the served clients remains fix, and the uses similar along the time. It is thus enough for the caches to adapt their content

and their operation to be effectively useful. In a mobile context, as the clients are regularly moving from one zone to another, topology is always fluctuating. A client used by a cache at time T may be out of reach at the next time step.

The integration of the mobility in the caches is a recent problem, and few solutions are exposed in the literature. Two families of solutions may be distinguished: an optimized co-operation of caches, which may imply a change of cache and a context switch where the caches become mobiles in order to follow displacements of the clients.

In Hadjiefthymiades and Merakos (2001), the authors place themselves within the framework of a cellular network in which mobile clients consult Web sites. In order to optimize the navigation of the clients as well as possible, the authors propose to insert a proxy-cache for each client within the system. This one is placed close to the user, at the level of the base stations, and stores a small set of Web pages and pictures useful for the navigation of the client. Its contents being limited, it can, at lower cost, move to follow the displacements of the client. This technique is interesting but requires that the whole end-side material (access point or base station) should be equipped with sufficient capabilities of calculation and storage. Moreover, the migration of a cache can raise the cost of the network if the stored documents are bulky, as within a video framework.

Some projects descend the level of the cache since it is placed on the client himself. Thus in Cohen, Herscovici, Petruschka, Maarek, and Soffer (2002), the authors use a cache placed on the mobile device, which is in charge of fetching a set of pages related to the navigation in progress, as soon as possible. The authors of Sailhan and Issarny (2003) present a system of caches for mobile clients functioning in *ad hoc* mode. This system is particularly useful for the users exploiting their wandering peripherals in zones where many other peers are. The example given is that of a museum offering a virtual visit thanks to personal assistants. In this architecture, the PDAs obtain their information on a server via access points disseminated through the museum. It may happen that no access point is within the range of a client. If a networked resource is to be reached, it is possible for this client to connect in *ad hoc* mode to terminals available in its neighbourhood, and to launch a strategy of exchange of cached information. This strategy is very interesting since the caches are placed on the same level as the clients, and the cooperative mechanism makes it possible to optimize the use of the bandwidth. However, it requires the use of peripherals having a significant storage capacity, and those must incorporate the cache program, which is not always possible.

Within the framework of video streaming, the mobility of the cache is hardly possible. Indeed, the volume of transmitted data being very significant, a cache migrating from one place to the other implies a very high cost of utilization. The mobility of the users have thus to be treated by optimized policies of inter-cache co-operations.

Handoff Policy to Tackle Mobility Between Caches

An optimized policy of cooperation of caches for the mobility of the users has a main function: to envisage the change of cache of the users because of their mobility. It is indeed useless to continue diffusion between a cache and a client which would have moved away too far from the former, when another more optimal cache could take over.

When a set of distributed caches is deployed, a paving of the territory in zones of diffusion can be imagined. The policy of cooperation must then supervise displacements of the client in order to detect a change of zone. This roaming from one zone to another may be compared to the change of terminal in mobile telephony or the wireless networks. One will then speak of handoff.

The first basic policy consists in carrying out no action whatsoever in any case. This corresponds to what currently occurs when no

policy is implemented. The problem that arises is the lack of reactivity in the event of a handoff. Indeed, when a user looking at a film changes zones, the cache, which must take over, does not have the sequence requested and was not advised of a possible arrival of the request. The diffusion must then stop while the part being streamed is fetched in the new cache.

The second basic policy (called "broadcast") consists in contacting all the neighbouring caches to advise them to fetch the currently streamed sequence. The defect of reactivity is thus smoothed out, each cache keeping the sequence in the event a user should arrive. However, this solution is not satisfactory because it quickly causes a clogging on the network between the caches and it uses disk space of the caches for sequences which have few chances to be used.

In order to optimize the transition when a client moves, thus causing a change of zones, the caches must cooperate by exchanging information with their "neighbours" and by prefetching part or whole of one or several sequences. An optimized management should thus define a set of caches sufficient at the same time to ensure a strong probability of hit while minimizing the disk space and the lost bandwidth.

Use of the Prediction of Position in Video Caches

To succeed in treating the handoff (i.e., the change of cache in a short time), compatible with the temporal constraints of the diffusion, and also by mobilizing only the necessary resources in order not to disturb too much the diffusion towards the other users, the system cannot be only reactive. The system of caches needs to anticipate this possibility and the potentially concerned caches should be all set to stream before the user changes zones. In addition, only a minimal number of caches should be included in this preventive measure in order not to put the scalability of the system in danger.

We propose to prefetch, in a reduced number of caches, the continuation of the sequence in the course of visualization of the users who are likely to change zones. With this purpose in mind, our technique is based on an observation of the mobility of the users, on a prediction of their short-term position and on the adequacy of each cache to serve the zones having to receive new users.

Our handoff policy is based on external information to anticipate the necessity of prefetching a cache. This information is of two types: the probability for a zone to receive a client in an immediate future, and the adequacy of the connections between the caches and the zones of reception. From this information we calculate an indicator evaluating the need to fetch the sequences.

When a client is in a given zone, we need to get the set of the probabilities of presence of the client in all nearby zones, at the next moment. Our policy is based on two view points resulting from the observation of former displacements: the observation, on the one hand, of the former moves carried out by the whole set of clients and,

Figure 3. Computation of the relevant pre fetching vector

$$\mathcal{M}_{(adequacy)} \times \vec{V_p} = \vec{V_e}$$

$$\begin{pmatrix} Cache_0 Zone_0 & \dots & C_0 Z_z \\ \vdots & \ddots & \vdots \\ C_c Z_0 & \dots & C_c Z_z \end{pmatrix} \times \begin{vmatrix} P_0 \\ \vdots \\ P_z \end{vmatrix} = \begin{vmatrix} e_0 \\ \vdots \\ e_c \end{vmatrix}$$

on the other hand, of those of the particular client. In order to refine the behaviour of the system, these two approaches are balanced thanks to an exponential average. We thus obtain a probability of presence for each close zone. At the end of this calculation, we present this set of probabilities in the form of a vector called *Vp* which dimension is the number of close zones plus 1 for the zone in progress. This last value, noted P0, represents the probability that the user will remain in the zone.

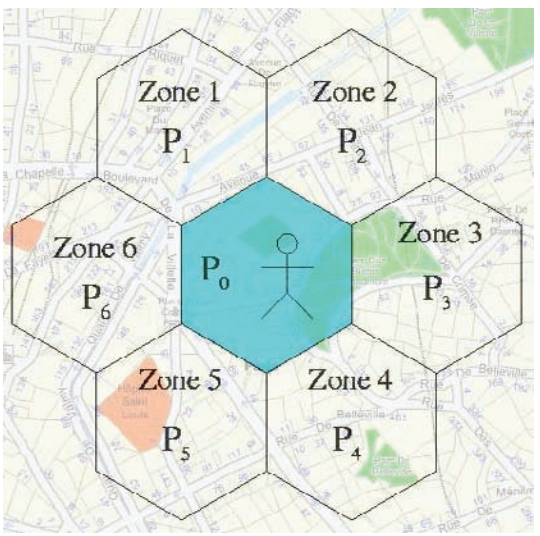
The adequacy between a cache and a zone is an indicator which quantifies the effectiveness with which a cache can stream a sequence towards a zone. The cache-zone adequacy does not take the availability of a particular sequence in a cache into account, but qualifies the quality of the connection. A simple example of quantifier is the average Round Trip Time between a cache and a zone. It is however necessary to integrate the variations of quality in the course of time, and to recompute this value regularly. These factors of adequacy are represented in the shape of a matrix binding each cache potentially useful for the diffusion to each zone, built in a distributed way thanks to exchanges between the caches.

That still remains to quantify the relevance of caches fetching. The columns of the matrix, representing the zones, are sorted in such way as to correspond to the lines of the vector *Vp*. Then, the vector *Ve* associating to each cache a quantity, which is the sum of the products of the cache-zone adequacies by the probability of presence of the user in the zone, is defined by the product of the matrix by the vector *Vp*. The resulting values of the vector are in a range from 0 to 1. Indeed, the vector of probability of presence is a probability distribution whose sum is equal to 1. The coefficients of the matrix of adequacy are, by construction, all ranging between 0 and 1. Thus, the sum of the products of the ones by the others also lies between 0 and 1. The larger the values of the resulting vector are, the most suited for streaming to a zone having a large probability of receiving a client a cache is.

Since we have an evaluation of the interest of fetching for each cache, we still have to define the level needed to load this cache. This threshold can be modulated in order to define the level of aggressiveness of the policy. For example, in order take a multi-layers stream into account (a basic stream and a complementary stream), a first variable HS = P0 * threshold will give the value of swing beyond which the entirety of flow will be charged, and a variable $Sb = a * HS$ makes it possible to define a range within which only the basic stream will be transferred. Lastly, if the evaluation is lower than Sb, nothing will be charged.

This method makes it possible to improve the fluidity of the diffusion towards mobile clients by being based on a short-term prediction of their future positions. Thanks to the dynamic construction of a matrix of adequacy between a set of caches and a set of zones of diffusion, and with the use of the probabilities of presence, we deduce an algorithm revealing the state in which the system will have to be at moment *T+1* will have to be. Analysing this algorithm will allow us

Figure 4. Territory partitioning in streaming zones



to set up a policy of total or partial prefetching of the sequences in the neighbouring caches.

GUIDE NUMÉRIQUE MOBILE: GUINUMO

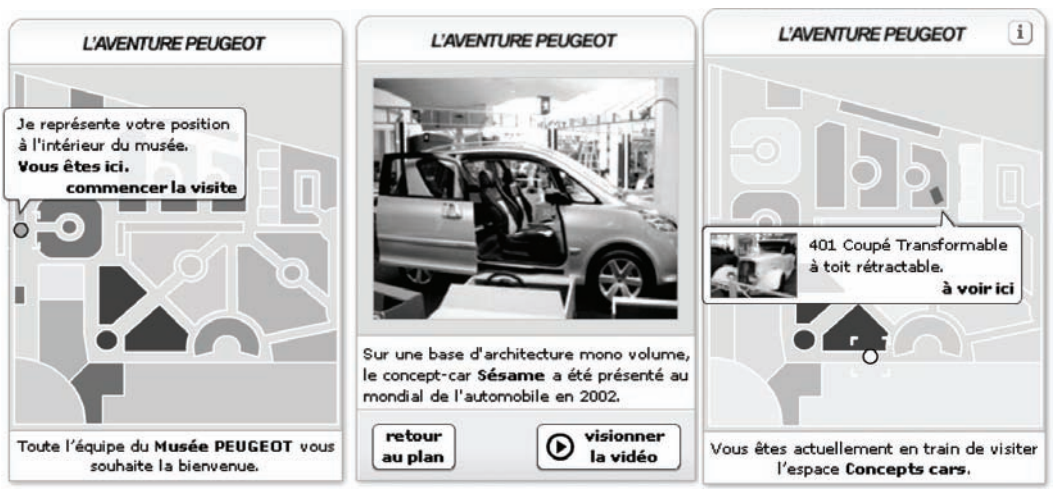
We have a demonstrator of the techniques we presented above. This product, called GuiNuMo, allows the assisted visit of the "Museum of the Peugeot Adventure." Our tool allows the geolocation of the visitor within the museum and the on-demand streaming of audio-visual content related to the environment they will come across. In Figure 4 you can see three GuiNuMo screenshots on a PDA. The picture on the left is that of the beginning of the visit; one discovers the plan of the museum and the position of the visitor, near to the entry. On the map of the museum the various zones of diffusion are shown. They are associated to themed elements of the museum (concept car, competition...). The screenshot in the middle presents the GuiNuMo interface when the user enters the zone called « concept car ». The presentation of a specific vehicle is offered and it is possible to play a video. The video, if requested, will be streamed from the cache dedicated to this zone.

During the whole visit, the position of the peripheral is computed in real time, and the available content is provided in the form of play lists that the user can choose to visualize or not. When it is possible, GuiNuMo suggests the visitor to go to a different area of the museum in order to discover objects in relation to the media he has just consulted. For example, at the end of a video depicting the "Peugeot 306 CC," GuiNuMo will suggest going to the part devoted to the "Peugeot 401 coupé transformable" which was, in 1933, the first car integrating a retractable roof. See screenshot 3 for a graphic representation.

All the actions of the visitor are recorded by the system in order to be able to analyze the visit and to feed the training algorithm. Moreover the visit can be studied by the staff of the museum to deduce some potential transformations. Indeed by analyzing the logs of the visits of multiple visitors, it is possible to note that few people visit certain sites in the museum or that a particular zone usually holds greater attention. Thus, the team of the museum may choose to rearrange spaces or to make recommendations in order to enlight under exploited spaces.

The training algorithm makes it possible to determine, statistically, the probability of visualization of each media according to the actions

Figure 5. Three screen shots of GUINUMO application interface



carried out previously. Consequently, it is possible to anticipate which media will probably be visualized soon. It is thus possible to prepare the system to allow a better reactivity.

Right now, the prediction is carried out as a whole. We are currently working on the identification of the profile of the users in order to obtain a prediction of better quality. Indeed, each visitor does not visualize all the available media, but operates a themed selection set. One can make a difference between the visitors interested in technology and those interested in the history of the Peugeot Company. By analyzing the first documents requested by the user, it is possible to determine to which group of users they belong and to subsequently direct the prediction and the recommendations according to the actions carried out previously by other users of the same class of equivalence.

CONCLUSION AND FUTURE TRENDS

In this chapter, we described the interest of the predictive methods during the broadcast of multimedia flows towards mobile terminals. These methods are integrated in location services as predictions and in the architecture as caches. Caches allow the scalability of the system and the storage of data to send to the client into the future probabilistic areas.

The location predictions based on the knowledge, allows the anticipation of the possible or probable areas of location. This method is included in the cache loading strategies as well as in the establishment and continuity of the terminal connection. The union of these two mechanisms allows a fast and accurate management of the access point migration when a terminal moves from one zone to another.

The intercache communication methods, called "cache sibling," are well-known algorithms. They make it possible to manage the content deletion in the distributed caches. They require to be adapted, to take into account the specificity of the video caches. Indeed, a video cache does not maintain strong coherence. It has to communicate with its "neighbours" to facilitate the continuity of the sequence broadcast.

The localization principle used in optical or hertzian ways is rather old. It is well adapted to outdoor spaces (e.g., on seas). It is possible to use two great classes of algorithms: the triangulation or the trilateration. For clients, in Wifi-like networks, we do not have access to angular information; it is thus the trilateration which is used. In the case of the indoor localization, corrections must be made to the coefficient of the Friis equation in order to take the absorption of the wave by the building elements into account.

The prediction methods of the mobile location can be based on two types of information: a topological knowledge of the area, allowing the identification of relevant trajectories, and experiences of the previous movements deduced from a position list, the future most probable positions. The experience can be limited to previous moves of the client which receives the flow or can combine information resulting from the movements of all the users having crossed the considered area. A relevant method consists in mixing general and individual information.

The GuiNuMo1 application which was presented in this chapter to illustrate our methods is installed in a museum for demonstration purposes. This experimental platform enables us to work on real scenarios and to observe the reactivity of the system. The collected information tends to ascertain the hypothesis that mobile multimedia applications are more and more accepted by users, and drive us to consider implementing new features.

Using caches as the broadcast infrastructure of multimedia flow is a significant point. We are now thinking of installing caches into the client device and of sharing content of these caches in an *ad hoc*, peer-to-peer network. This method should allow under-dimensioning, possibly ever to remove the cache from the broadcast infrastruc-

ture, in order to rely strictly the mobile devices. In case of numerous clients, the requirement of caches is important. The available space and the density of redundant data are linked to the number of clients which will allow scalability.

The vertical handoff is a research topic currently studied by a great number of international teams. It is the opportunity to switch from a network to another, keeping a connection continuity of the current applications. Basically, the IP protocol does not offer such service, and mobileIP allows only a discrete mobility, which means without any continuity on the current connections. To achieve a goal of continuity, it is necessary to adapt or modify the TCP/IP stack of the terminal and the servers. It is also possible to modify the TCP/IP stack of a network device near the client as the access-point, in place of the servers, in order to manage this problem. The vertical handoff must integrate a policy of network selection. In fact, it is important to select the right network, which means the network with the best bandwidth. But, with this strategy, we do not have the opportunity to choose the best available throughput. In order to do so, it is necessary to dynamically choose the best network, causing additional handoff in case of network overloads. Moreover, it will be possible to connect few networks at the same time in order to have a sum of download or upload throughputs using a multi path strategy.

The step after the vertical handoff will study the management of network failures mainly due to white spots using strategies of mobile perfecting. This technique will allow to load in advance some documents during the connected times in order to deliver them latter even if a failure network occurs during the request of view.

KEY TERMS

Ad Hoc Mode: Every client can talk to each other on a peer-to-peer basis.

Admission Policy: Algorithm used when a new client wants to fetch data from a cache to decide if the cache has sufficient capabilities left to serve him.

Cache: A cache gathers the functions of a server and of client. It takes place between them and can store and deliver popular documents. Being near the client, it helps resolve the problems of bottlenecks and increase reactivity.

Cooperation Policy: Used between distributed caches to cooperate and share data.

Handoff: Name of the mechanism which takes place when a user is roaming.

Insertion Policy: Algorithm of caches, decides which documents should be stored.

Mobile Network: Network in which part or all of the components are mobile.

Mobile Terminal: Every apparatus light-enough to be humanly transported and with embedded computation power, like laptops, PDA, new generation mobile phones.

Mobility: The action to move. We are interested in particular in the logical mobility (change of network, BTS, etc.) triggered by the geographical move (the action of changing physical coordinates in space).

Prefetch: Inserting documents into a cache in the hope that they are going to be requested in a near future to reduce start latency for the user. Contrarily to normal insertion, it is not triggered by clients.

Removal Policy: Management algorithm of caches, decides which stored documents should be deleted to make room for new and more popular documents.

Roaming: Action of a human moving from one zone to another.

Service Continuity: Property of a service over a mobile network. When continue, a service is not interrupted by changes in its logical position (change of AP / BTS). For example in the GSM standard, as long as you stay in covered areas, phone conversations are not interrupted when you change your BTS.

Sibling: Exchange of data between two caches.

Signal Strength: It is the power of the signal measured.

Start Latency: Time elapsed between the moment where a user requests of a document and the time it is displayed on its peripheral.

Streaming: Technique of transfer in a continuous flow to allow the display of the media while downloading.

Video Cache: A cache with specific policies, optimized for the delivery of video data.

INTRODUCTION

The heterogeneous network environment that Internet provides to real time applications as well as the lack of sufficient QoS (quality of service) guarantees, many times forces applications to embody adaptation schemes in order to work efficiently. In addition, any application that transmits data over the Internet should have a friendly behaviour toward the other flows that coexist in today's Internet and especially toward the *TCP* flows that comprise the majority of flows. We define as TCP friendly flow, a flow that consumes no more bandwidth than a TCP connection, which is traversing the same path with that flow (Pandhye, Kurose, Towsley, & Koodli, 1999).

During the multicast transmission over the Internet, several aspects need to be considered:

- **Transmission rate adaptation:** The sender must adapt the transmission rate based on the current network conditions.
- **TCP friendliness:** During the multicast transmission over the Internet, the multicasts flows must be TCP-friendly.
- **Scalability:** The performance of the adaptation scheme must not deteriorate with increasing numbers of receivers.

- **Heterogeneity:** The adaptation scheme needs to take into account the heterogeneity of the Internet and must aim at satisfying the requirements of a large part of the receivers if not all possible receivers.

BACKGROUND

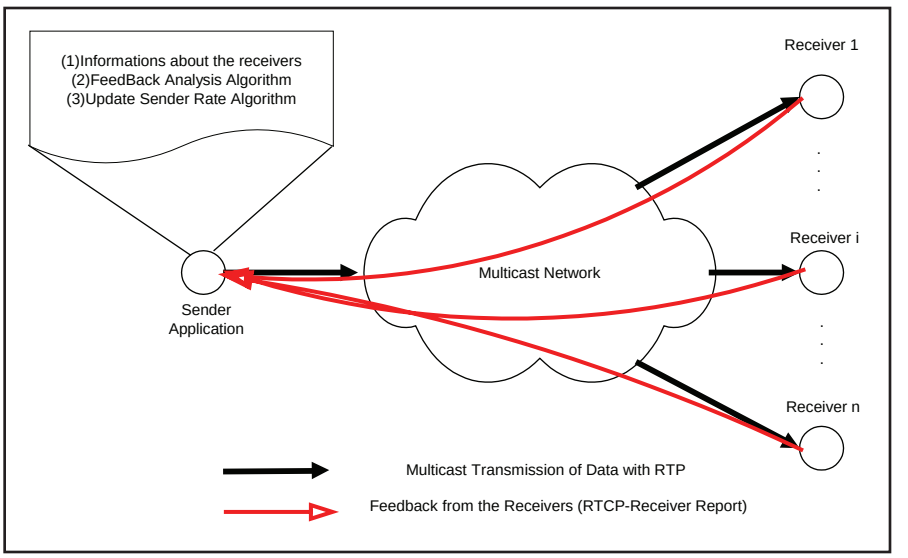
When someone multicasts multimedia data over the Internet, he or she has to accommodate receivers with heterogeneous data reception capabilities. To accommodate heterogeneity, the sender application may transmit one multicast stream and determine the transmission rate that better satisfies most of the receivers, may transmit at multiple multicast streams with different transmission rates and allocate receivers at each stream, or may use layered encoding and transmit each layer to a different multicast stream.

The single multicast stream approach has the disadvantage that clients with a low bandwidth link will always get a high-bandwidth stream if most of the other members are connected via a high bandwidth link and vice versa. The previously described problem can be overcome with the use of a multi-stream multicast approach. Single multicast stream approaches have the advantages of easy encoder and decoder implementation and simple protocol operation, due to the fact that during the single multicast stream approach there is no need for synchronisation of receivers' actions (as is required for the multiple multicast streams and layered encoding approaches).

The methods proposed for the multicast transmission of multimedia data over the Internet can be generally divided in three main categories, depending on the number of multicast streams used:

- The sender uses a single multicast stream for all receivers (Bouras & Gkamas, 2003). This results to the most effective use of the network resources, but on the other hand the fairness problem among the receivers arises, especially when the receivers have very different capabilities. The subject of adaptive multicast of multimedia data over networks with the use of one multicast stream has engaged many researchers. During the adaptive multicast transmission of multimedia data in a single multicast stream, the sender application must select

Figure 1. Architecture of a single stream multicast transmission mechanism



the transmission rate that satisfies most of the receivers with the current network conditions. Three approaches can be found in the literature for the implementation of the adaptation protocol in a single stream multicast mechanism: equation based (Pandhye et al., 1999), network feedback based (Jiang, Ammar, & Zegura, 1998; Sisalem, 1998) or based on a combination of the previous two approaches (Sisalem & Wolisz, 2000a).

- **Simulcast:** The sender transmits versions of the same video, encoded in varying degrees of quality. This results to the creation of a small number of multicast streams with different transmission rates (Bouras, Gkamas, Karaliotas, & Stamos, 2001). The different multicast streams carry the same video information but in each one the video is encoded with different bit rates, and even different video formats. Each receiver joins in the stream that carries the video quality, in terms of transmission rate, that it is capable of receiving. The main disadvantage in this case is that the same multimedia information is replicated over the network but recent research has shown that under some conditions simulcast has better behavior that multicast transmission of layered encoded video (Kim & Ammar, 2001).
- The sender uses *layered encoded* video, which is video that can be reconstructed from a number of discrete data layers, the basic layer, and more additional layers, and transmits each layer into different multicast stream (Legout & Biersack, 2000; Sisalem & Wolisz, 2000b). The basic layer provides the basic quality and the quality improves with each additional layer. The receivers subscribe to one or more multicast streams depending on the available bandwidth into the network path to the source.

SINGLE STREAM MULTICAST TRANSMISSION OF MULTIMEDIA DATA

In such mechanism a sender application transmits multimedia data to a group of n receivers with the use of multicast in one stream. The sender application is using *RTP*/*RTCP* protocols for the transmission of the multimedia data. Receivers receive the multimedia data and inform the sender application for the quality of the transmission with the use of RTCP receiver reports. The sender application collects the RTCP receiver reports, analyses them and determines the transmission rate that satisfy most the group of receivers with the current network conditions.

During the single stream multicast transmission the sender usually runs two algorithms:

- **Feedback analysis algorithm:** Feedback analysis algorithm analyses the feedback information that the receivers sends to the sender application (most mechanisms use RTCP receiver reports for this purpose), concerning the transmission quality of the multimedia data. Every time the sender application receives feedback from a receiver, it runs the feedback analysis algorithm in order to estimate the preferred transmission rate, which will satisfy that receiver. The receiver's preferred transmission rate represents the transmission rate that this receiver will prefer if it was the only one receiver in the multicast transmission of the multimedia data.
- **Update sender rate algorithm:** The sender application in repeated time periods estimates the transmission rate for multicasting the multimedia data with the use of the update sender rate algorithm. The estimation of the sender application transmission rate is aiming to increase

the satisfaction of the group of receivers. When the sender application estimates the new transmission rate, it tries to provide to the group of receivers the best satisfaction that the current network conditions allow.

SIMULCAST

In such a mechanism, the server is unique and responsible of:

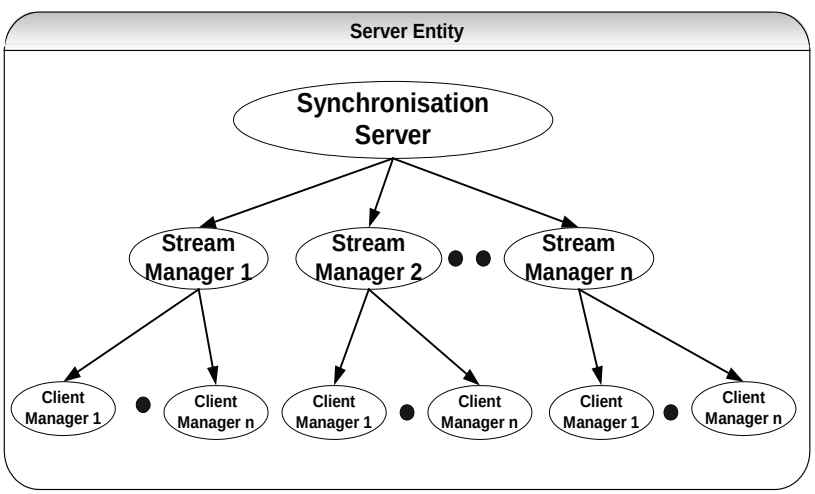
- Creating the n different multicast streams (in most mechanisms a small number of multicast streams, usually 3 or 4 are enough)
- Setting each stream's bandwidth limits
- Tracking if there are any clients that are not handled with fairness
- Providing the mechanisms to the clients to switch streams whenever they consider that they should be in another stream closer to their capabilities

Figure 2 shows the organisation and the architecture of the server entity. The server generates n different stream managers. In each stream manager**,** an arbitrary number of client managers is assigned. Each client manager corresponds to a unique client that has joined the stream controlled by this stream manager. The synchronisation server is responsible for the management, synchronisation, and intercommunication between stream managers.

The stream manager entity is responsible for the maintenance and the monitoring of one of the n different multicast streams. Also the stream manager entity has all the intra-stream adaptation mechanisms for the adjustment of the transmission rate. The stream manager periodically gathers the states reported by all client managers belonging to it at the end of a specific, fixed time period. It then uses an appropriate algorithm that tries to improve fairness between clients by determining whether a lower or a higher bit rate is more appropriate. Whenever a client cannot be satisfied by a stream due to the fact that most of the other clients have much higher or much lower reception capabilities, the stream manager informs it that it has to move to a lower or higher quality stream.

Each client manager corresponds to a unique client (for scalability issues a small representative group of clients may have a corresponding client manager). It processes the RTCP reports generated by the client and can be considered

Figure 2. The architecture and the data flow of the server



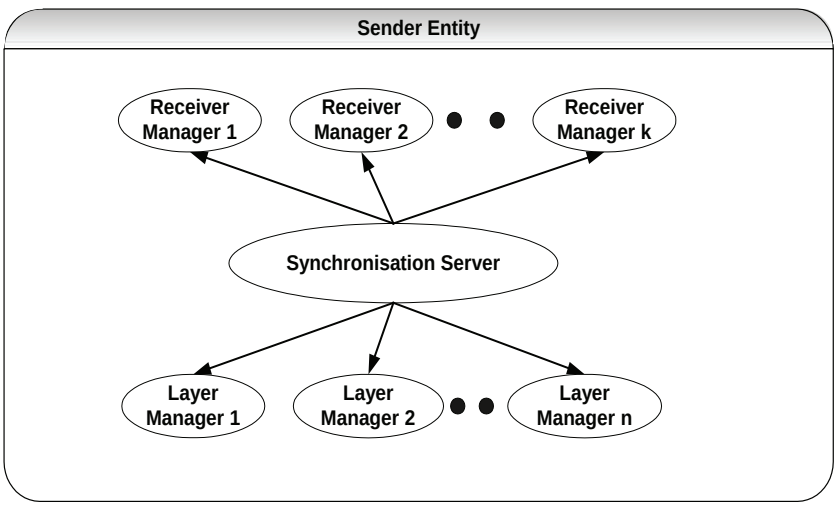
as a representative of the client at the side of the server. It can interact only with one stream manager at a given time, the stream manager controlling the stream from which the client is receiving the video. Client manager receives the RTCP reports from the client and processes them based on packet loss rate and delay jitter information. It then makes an estimation of the state of the client, based on the current and a few previous reports that it stores in a buffer.

LAYERED ENCODING

In such mechanism, the sender transmits multimedia data to a group of m receivers with the use of multicast. The sender is using the layered encoding approach, and transmits the video information in n different layers (the basic layer and n-1 additional layers). The sender transmits each layer into a different RTP/RTCP multicast session. The transmission rate within each layer is adapting within its limits (each layer has an upper and lower limit in its transmission rate) according to the capabilities of the receivers listening up to it. The receivers join the appropriate number of layers which better suit their requirements (available bandwidth between the sender and the receiver, etc) and if during the transmission of multimedia data the network conditions to the path between them and the sender change, the receivers have the capability to receive more or less video layers in order to accomplish better their requirements. The communication between the sender and the receivers is based on RTP/RTCP sessions and the sender is using the RTP protocol to transmit the video layers and the participants (the sender and the receivers) use the RTCP protocol in order to exchange control messages.

Figure 3 shows the organisation and the architecture of the sender entity. The sender generates n different layer managers. Each layer manager is responsible for the transmission of a video layer. The sender creates a new receiver manager every time receives a RTCP report from a new receiver. Each receiver manager corresponds to a unique receiver (for scalability issues a small representative group of receivers may have a corresponding receiver manager). It processes the RTCP reports generated by the receiver and can be considered as a representative of the receiver at the side of the sender. In addition, the synchronisation server is responsible for the management, synchronisation and intercommunication between layer managers

Figure 3. The architecture and the data flow of the sender



and receiver managers. If a receiver manager does not receive RTCP reports from the receiver which it represents for a long time, it stops its operation and releases its resources.

Each receiver measures the characteristics of the path, which connects it with the sender and informs the sender with the use of receiver reports.

EVALUATION PARAMETERS

During the multicast transmission of multimedia data over the Internet the overall target is the optimal usage of the network resources and for this reason an appropriate mechanism is used. In order to evaluate those mechanisms there are the following criteria:

- **Network congestion:** The goal of the multicast transmission mechanisms is to increase the usage of the available bandwidth and decrease the packet losses of all the applications that transmit data in the same network path with the network path of the multicast data.
- **Scalability:** During the multicast transmission of multimedia data, the multimedia data may be received by a large number of receivers. The performance of the selected mechanism must not be downgraded when the number of the receivers of the multicast data is increased. This means that the complexity and the performance of the used mechanism must be acceptable even when a large number of receivers receive the multimedia data through the multicast transmission.
- **Adaptation speed:** With the term adaptation speed we refer to the time needed from the begging of the multicast transmission of the multimedia data until the selected mechanism achieves a stable operation. This time must be relatively small and the performance of the mechanism is better when this time is small.
- **TCP friendliness:** Most of the Internet traffic is TCP traffic. Any application that transmits data over the Internet should have a friendly behaviour toward the other flows that coexist in today's Internet and especially toward the TCP flows that comprise the majority of flows.
- **User satisfaction:** It is difficult to measure the user satisfaction. For example, studies has show that during the transmission of MPEG video, just 3% packet loss can result up to 30% reduction of the presentation quality. As a result the satisfaction of the end user is influenced very much from the packet loss.

TRANSMISSION OF MULTIMEDIA DATA

The transmission of the multimedia data is based on the protocols RTP/RTCP. The protocol RTP is used for the transmission of the multimedia data from the server to the client and the client uses the RTCP protocol, in order to inform the server of the transmission quality.

The RTP/RTCP protocols have been designed for the transmission of real time data like video and audio. Although the RTP/RTCP protocols were initially designed for multicast transmission, they were also used for unicast transmissions. RTP/RTCP can be used for one-way communication like video on demand or for two-way communication like videoconference. RTP/RTCP offers a common platform for the representation of synchronisation information that real time applications need. The RTCP protocol is the control protocol of RTP. The RTP protocol has been designed to operate in cooperation with the RTCP protocol, which provides information about the transmission quality.

RTP is a protocol that offers end to end transport services with real time characteristics over packet switching networks like IP networks. RTP packet headers include information about

the payload type of the data, numbering of the packets and timestamping information.

RTCP offers the following services to applications:

- **QoS monitoring:** This is one of the primary services of RTCP. RTCP provides feedback to applications about the transmission quality. RTCP uses sender reports and receiver reports, which contain useful statistical information like total transmitted packets, packet loss rate and delay jitter during the transmission of the data. This statistical information is very useful, because it can be used for the implementation of congestion control mechanisms.
- **Source identification:** RTCP source description packets can be used for identification of the participants in a RTP session. In addition, source description packets provide general information about the participants in a RTP session. This service of RTCP is useful for multicast conferences with many members.
- **Inter-media synchronisation:** In real time applications it is common to transmit audio and video in different data streams. RTCP provides services like timestamping, which can be used for inter-media synchronisation of different data streams (for example synchronisation of audio and video streams).

More information about RTP/RTCP can be found in RFC 3550 (Schulzrinne, Casner, Frederick, & Jacobson, 2003).

FUTURE TRENDS

The mechanisms described in the previous paragraphs have been proposed for installation and operation over the Internet. One interesting extension of the previous mechanisms is the adaptation of the previous mechanisms to operate over mobile networks. The multicast transmission of multimedia data over mobile networks is a challenge due to the fact the one of the basic characteristics of mobile networks is the continuously changing environment. In order to adapt the previously described mechanisms for usage over mobile networks various issues must be considered such as more efficient encodings.

CONCLUSION

The multicast transmission of real time multimedia data is an important component of many current and future emerging Internet applications such as videoconferencing, distance learning, and video distribution. The heterogeneous nature of the Internet makes the multicast transmission of real time multimedia data a challenge. Different receivers of the same multicast stream may have different processing capabilities, different loss tolerance and different bandwidth available in the paths leading to them.

When multicast multimedia data is transmitted over the Internet, receivers with heterogeneous data reception capabilities have to be accommodated. To accommodate heterogeneity, the sender application may transmit one multicast stream and determine the transmission rate that satisfies most of the receivers, it may transmit at multiple multicast streams with different transmission rates and allocate receivers at each stream or it may use layered encoding and transmit each layer to a different multicast stream.

KEY TERMS

Layered Encoding: Transmission of the multimedia data in n different layers the basic layer and n-1 additional layers.

Multicast: Transmitting data simultaneously to many receivers without the need to replicate the data.

Multimedia Data: Multimedia data refers to data that consist of various media types like text, audio, video, and animation.

Quality of Service (QoS): Quality of service refers to the capability of a network to provide better service to selected network traffic.

RTP/RTCP: Protocol that is used for the transmission of multimedia data. The RTP performs the actual transmission and the RTCP is the control and monitoring transmission.

Simulcast: Transmission of the same multimedia data in multiple multicast streams with different transmission rates.

Chapter 8.13
IP Multimedia Subsystem (IMS) for Emerging All-IP Networks

Muhammad Sher
Technical University of Berlin, Germany

Fabricio Carvalho de Gouveia
Technical University of Berlin, Germany

Thomas Magedanz
Technical University of Berlin, Germany

INTRODUCTION AND BACKGROUND

Today the traditional telecommunication technology is declining because of popularity and increasing demand of voice over IP (VoIP) due to the reason that deployment, maintenance, and operation of data networks based on IP infrastructure are less costly than the voice networks. Consequently, it is straightforward to think relaying all types of communications on data networks rather than maintaining in parallel two network technologies. On the other hand, today we see increasing demand of *integrated multimedia services*, bringing together Internet applications with telecommunications. In prospect of these global trends, the mobile communications world has defined an all-IP network vision within the evolution of cellular systems, which integrates cellular networks and Internet. This is the IP multimedia system (IMS) (3GPP, TS 23.228, 2005), namely overlay architecture for provisioning of multimedia services such as VoIP and videoconferencing on top of globally emerging 3G broadband packet networks.

In the face of the IP network vision, namely the use of fixed and mobile IP networks for both data and voice/multimedia information looking for the target service control architecture. The IMS is an approach to provide overlay service delivery platform (SDP) (Magedanz & Sher, 2006) architecture for IP networks, entirely built on Internet protocols defined by the Internet engineering task force (IETF), which have been extended on request of 3GPP (Third Generation Partnership Project) to support telecommunications require-

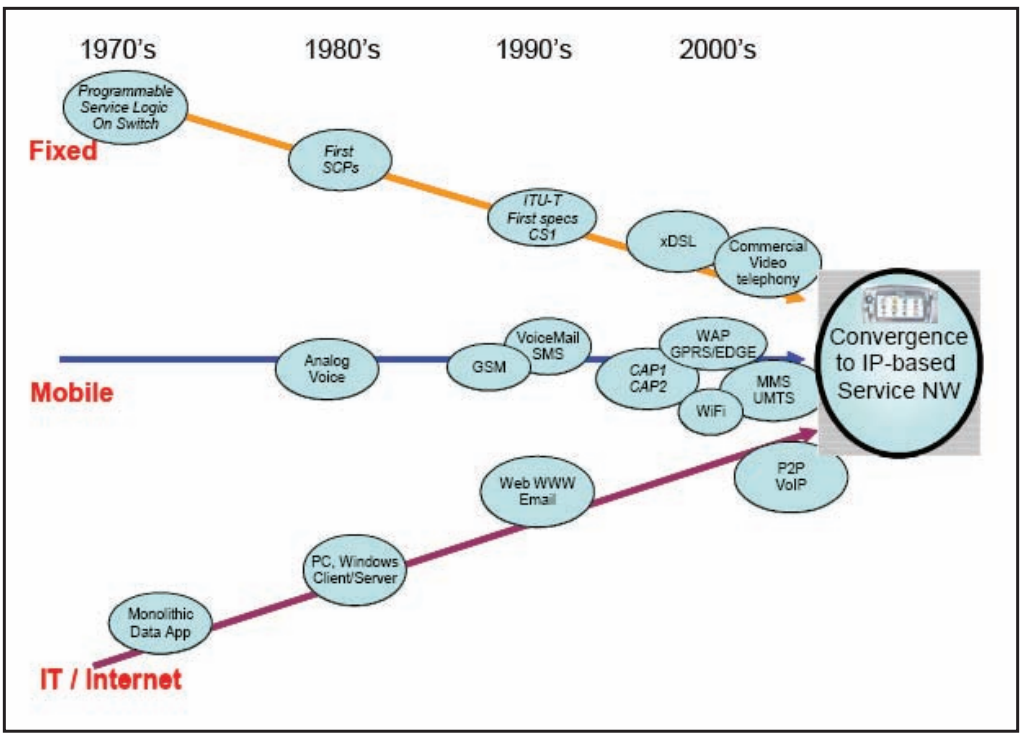
ments such as security, accountability, quality of service, etc. Mobile operators today face the problem that mobile users can gain access to the Internet and make use of Internet services such as *instant messaging*, *presence*, chat, content download, etc. On the other hand, the operators define a minimum SDP architecture for providing QoS, security, and charging for IP-based services, while providing maximum flexibility for the realization of value added and content services.

EVOLUTION TOWARD CONVERGED NETWORKS

The communication era is passing through the evolutionary phase of fixed-mobile convergence (FMC) and *voice-data integration* as shown in Figure 1, and IMS is considered a common platform for FMC granting convergence and compatibility between fixed/mobile networks, multimedia, and converged services support, and providing key community service enablers such as group management, *presence*, IM/PoC, and generic VoIP/MMoIP support (Magedanz, 2005).

In face of such convergence, the need for universal service delivery platforms (SDPs) supporting integrated services emerged. This means that SDP should, in principle, enable the rapid and uniform programming and provision of seamless multimedia services on top of any network environment. There is no doubt, however, that today two main trends are of pivotal importance for SDPs design, namely the support of mobile users and the support of (mobile) multi media data services.

Figure 1. Toward fixed-mobile-internet convergence



IMS MOTIVATION AND STANDARDIZATION

IMS is designed to provide fancy and attractive Internet services everywhere using mobile networks based on IP protocols and standards with emphasis on QoS, dynamic charging, and integration of different services and roaming facility on reasonable service charges. The IMS provides easy and efficient ways to integrate different services, even from third parties, and enables the *seamless integration* of legacy services and is designed for consistent interactions with circuit switched domains. The IMS manages event-oriented quality of service policies (e.g., use of VoIP and HTTP in a single session—VoIP has QoS, HTTP is best effort). These systems (IMSs) also have event-oriented charging mechanism policies--means change specific events on the appropriate level. If two events need the same IP resources we may charge them differentially for the same user in the same session (Poikselkae, Mayer, Khartabil, & Niemi, 2004). These characteristics make IMS the future technology in a comprehensive service and application-oriented network.

The IMS has been standardized since the beginning of this century within Release 5 and extended in Release 6 within 3GPP and 3GPP2 (Third Generation Partnership Project 2) focus to UMTS/CDMA2000 data packet networks. The Release 5 standards have been driven by the vision to define the IMS for providing multimedia services including VoIP. The IMS is supposed to be standardized access-independent IP-based architecture that interworks with existing voice and data networks for fixed (e.g., PSTN, ISDN) Internet and mobile users (e.g., GSM, CDMA). The IMS architecture makes it possible to establish peer-to-peer IP communications with all types of clients with quality of services and complete service delivery functionalities.

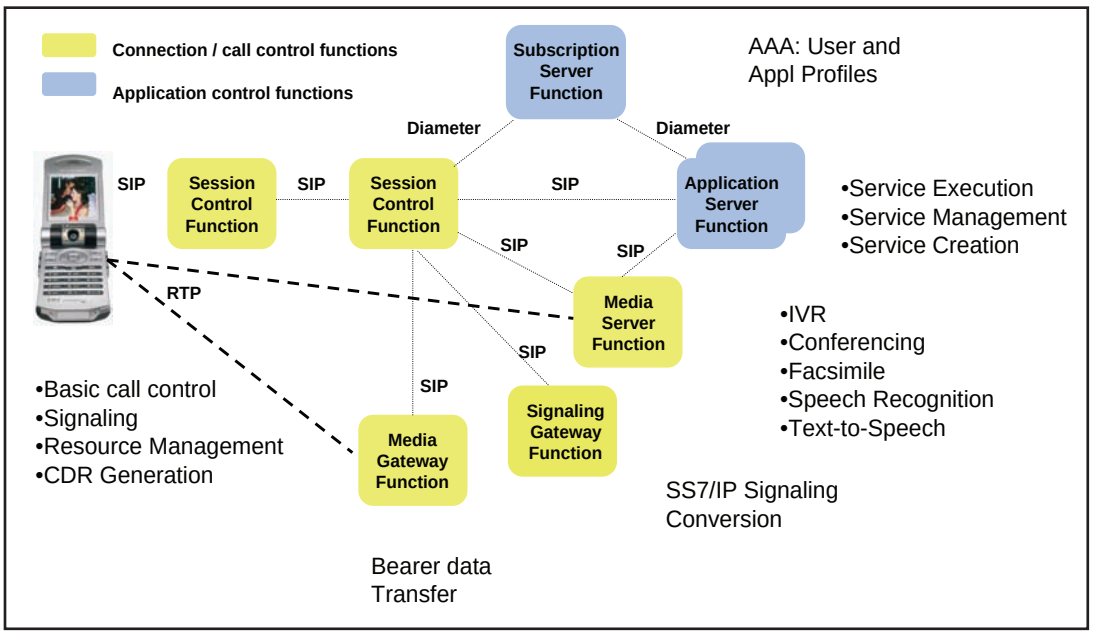
IMS Release 6 is fixing the shortcomings in Release 5 and also contains novel features like *presence*, messaging, conferencing, group managements and local services. Release 6 has optimized the IMS to provide the envisaged IMS killer application push-to-talk (over cellular). The IMS has been planned for deployment in 3G wireless networks around 2006. It also provides additional security features like confidentiality protection of *SIP* messages, usage of public key infrastructure, and subscriber certificates.

In addition, since 2004 ETSI *TISPAN* (Telecommunication and Internet converged Services and Protocols for Advanced Networking) is looking at service infrastructures for fixed-mobile convergence and next generation networks, which extends the IMS to make it applicable on top of various access networks (i.e., WLANs and particular for fixed Internet (DSL)). The recent IMS Release 7 is a joint cooperation work of 3GPP and TISPAN addressing all IP networks infrastructure.

IMS ARCHITECTURE AND KEY COMPONENTS

The IMS defines service provision architecture and it can be considered as the next generation service delivery platform framework. It consists of modular design with open interfaces and enables the flexibility for providing multimedia services over IP technology. IMS does not standardize specific services but uses standard service enablers (e.g., *presence* inherently supports multimedia over IP and VoIP) (Magedanz et al., 2006). In IMS architecture, SIP protocol (IETF, RFC 3261, 2002) is used as the standard signaling protocol that establishes controls, modifies, and terminates voice, video, and messaging sessions between two or more participants. The related signaling servers in the architecture are referred to as call state control functions (CSCFs) and distinguished by their specific functionalities. It is important to note that an IMS compliant end user system has to provide the necessary IMS protocol support, namely SIP, and the service related media codecs

Figure 2. IMS high level functional diagram



for the multimedia applications in addition to the basic connectivity support (e.g., GPRS, WLAN, etc.). Figure 2 displays a generic IP-based IMS functional diagram.

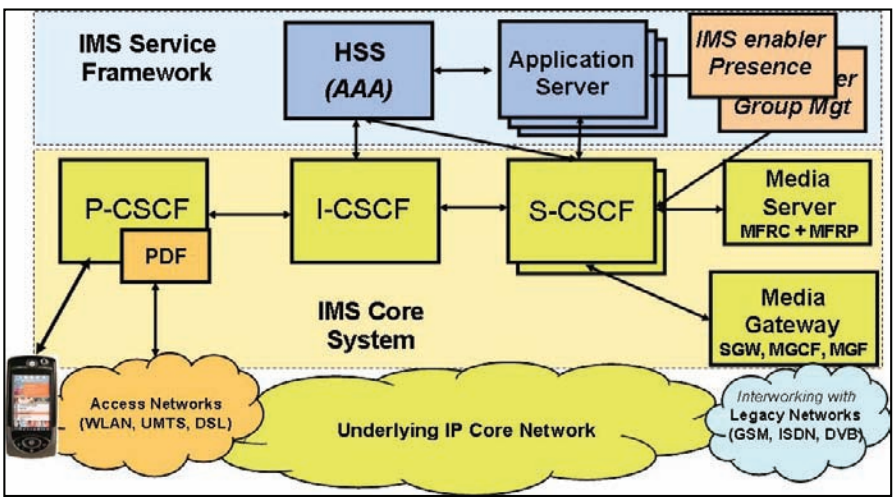
The functionality related to authentication, authorization, and accounting (AAA) within the IMS is based on the IETF *diameter* protocol (IETF, RFC 3588, 2003) and is implemented in the home subscriber system (HSS), CSCFs, and various other IMS components in order to allow charging functionality within the IMS. Instead of developing the protocol from scratch, diameter is based on the *remote authentication dial in user service* (RADIUS), which has previously been used to provide AAA services for dial-up and terminal server across environments. The other protocol, which is important for multimedia contents, is *real-time transport protocol* (RTP), which provides end-to-end delivery for real-time data. It also contains end-to-end delivery services like payload-type (codec) identification, sequence numbering, time stamping, and delivering monitoring for real-time data. RTP provides QoS monitoring using the RTP control protocol (RTCP), which conveys information about media session participants.

The IMS entities and key functionalities can be classified in six categories--session management and routing family (CSCFs), databases (HSS, SLF), interworking elements (BGCF, MGCF etc.), services (application server, MRCF, MRFP), support entities (THIG, SEG, PDF) and charging (Poikselkae et al., 2004). Now we describe the most important components and parts of IMS architecture:

- **Proxy Call State Control Function (P-CSCF):** It is the first contact point within IP multimedia core network subsystem. Its address was discovered by UEs following packet data protocol (PDP) context activation. The P-CSCF behaves like a proxy accepting requests and services them internally or forwards them. It performs functions like authorizing the bearer resources for the appropriate QoS level, emergency calls, monitoring, header (de)compression, and identification of I-CSCF.

- **Interrogating Call State Control Function (I-CSCF):** It is the contact point within an operator's network for all connections destined to a subscriber of that network operator, or a roaming subscriber currently located within that network operator's service area. There may be multiple I-CSCFs within an operator's network. I-CSCF performs functions like assigning an S-CSCF to a user performing SIP registration/charging and resource utilization (i.e., generation of charging data records (CDRs)/acting as a topology hiding inter-working gateway (THIG)).
- **Serving Call State Control Function (S-CSCF):** It performs session control services for the endpoint and maintains session state as needed by network operator for support of services. Within an operator's network, different S-CSCFs may have different functionality. The important functions performed by S-CSCF includes user registration/interaction with services platforms for the support of services. The S-CSCF decides whether an application server is required to receive information related to incoming SIP session request to ensure appropriate service handling. The decision at the S-CSCF is based on filter information received from the HSS. This filter information is stored and conveyed on a per application server basis for each user.
- **Home Subscriber Server:** HSS is equivalent to HLR (home location register) in 2G systems but is extended with two diameter-based reference points. It is the master database of an IMS that stores IMS user profiles including individual filtering information, user status information, and application server profiles.
- **Application Servers:** It provides service platform in IMS environment. It does not address how multimedia/value added applications are programmed but only well defined signalling and administration interfaces (ISC and Sh), and SIP and Diameter protocols are supported. This enable developers to use almost any programming paradigm within a SIP AS such as legacy intelligent network servers (i.e., CAMEL support environments), OSA/Parlay servers/gateways, or any proven VoIP SIP programming paradigm like SIP Servlets, call programming language (CPL) and common

Figure 3. IMS components and architecture



gateway interface (CGI) scripts, etc. The SIP AS is triggered by the S-CSCF, which redirects certain sessions to the SIP AS based on the downloaded filter criteria or by requesting filter information from HSS in a user-based paradigm. The SIP AS itself comprises filter rules to decide which of the applications deployed on the server should be selected for handling the session. During execution of service logic it is also possible for SIP AS to communicate with HSS to get additional information about a subscriber or to be notified about changes in subscriber profile.

- **Media Processing:** The media resource function (MRF) can be split up into media resource function controller (MRFC) and media resource function processor (MRFP). It provides media stream processing resources like media mixing, media announcements, media analysis, and media transcoding as well speech (Poikselkae et al., 2004). The other three components are border gateway control function (BGCF), media gate control function (MGCF) and Media gate (MG), which perform bearer interworking between RTP/IP and bearers used in the legacy networks.
- **IMS End User System:** It is important to note that an IMS compliant end user system has to provide the necessary IMS protocol support, namely SIP, and service related media codecs for multimedia applications in addition to the basic connectivity support (e.g., GPRS, WLAN, etc.).

IMS FEATURES AND SERVICES

The IMS is designed to provide number of key capabilities required to enable new IP services via mobile and fixed networks. The important key functionalities, which enable new mobile IP services, are:

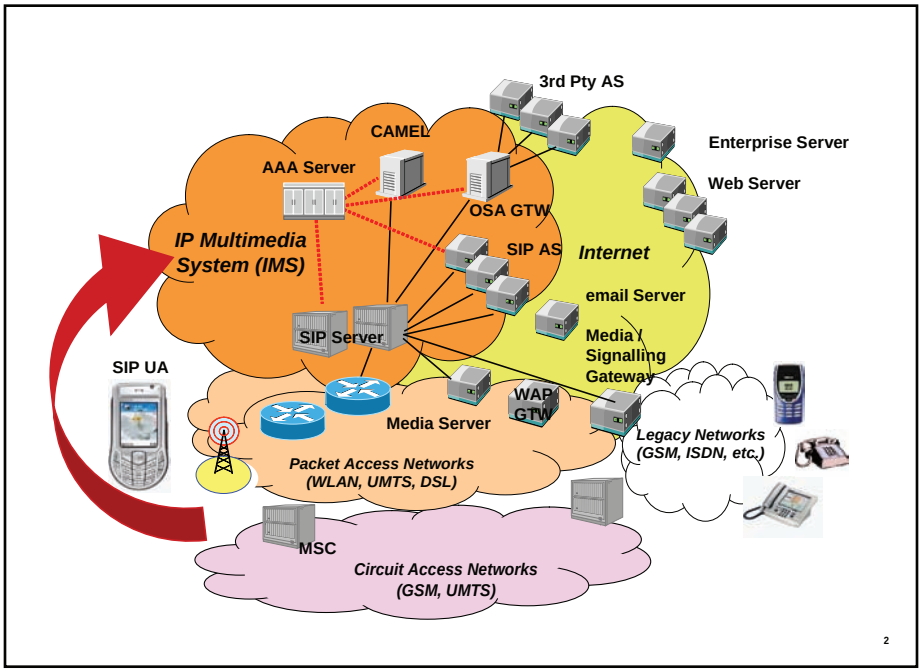
- Multimedia session negotiation and management
- Quality of service management
- Mobility management
- Service execution, control, and interaction

The IMS services are assumed to be addressed by open mobile alliance (OMA), which was created by WAP Forum in June 2002 with open mobile architecture objective and consists of more than ten mobile industries. The OMA SIP-based service enablers are specified on top of IMS as common platform (e.g., presence and group management etc.) as shown in Figure 4.

The important services provided by IMS are:

- **Push-to-talk (PTT) over cellular (PoC):** The PoC is *1-to-n* half-duplex communication and the key PTT functions include presence, group list management, PTT media processing, and PTT application logic (including floor control handling). These are bundled tightly together in the vendor-specific PoC deployments, but from 2006 onwards, IMS-based PTT implementation will be deployed. The idea is to enable the reuse of PTT core ingredients for other service offers, such as presence-based services. PoC content are short, instructional, and immediate.
- **Multimedia conferencing and group chat:** It is real time communication providing functionality about reservation and scheduling, document sharing and whiteboard facility, additional group or 1-to-1 chat, and instant messaging availability.
- **Click to dial:** When a user clicks on the screen button, IMS will negotiate and eventually set up automatically a voice session with one or more other users.
- **Dynamic push service:** Allow users to receive disable information based on many factors (e.g., preference, presence, geographic location, device type, and capabilities).

Figure 4. IMS as multimedia service enabler



OPEN ISSUES AND FUTURE TRENDS

The new multimedia services are a demanding combination of service capability features. Most likely upcoming services will also rely on features like presence, group-list management, additional logic, and other features on operator network (e.g., location, SMS, MMS). It is obvious that service capability features must be reused for scalability and capital expenses reasons. The future trends are:

- How to manage and orchestrate services
- How to create stringent services that bundle service capability features
- How to operate the network for services in a secure way

As mentioned in 3GPP specifications, the adoption of OSA/Parlay (parlay open service architecture) concepts and technologies can contribute a lot. OSA/Parlay already provides an industry standard that enables unified access with gateway character to service capability features of operators' network. Even secure access by third parties can be handled by the OSA/Parlay framework. This framework may control resources by assuming there is secure access for third parties network.

Recently, there are many IMS pre-products originating from VoIP and wireless telecommunications market. But, there is not yet any commercial IMS deployment within operator networks. However, first push to talk (PTT) service implementations mushrooming around the globe can be regarded as the first big trials for IMS technologies. However, there are still many open issues within IMS architecture and the 3GPP IMS standardization is ongoing, particular in the field of applying the IMS on top of different access networks (i.e., WLAN, WIMAX, and DSL) and IMS evolution toward an all-IP network.

CONCLUSION

The IP multimedia subsystem (IMS) defined by the 3rd Generation Partnership Projects (3GPP) and multimedia domain (MMD) by 3GPP2 is today considered the global service delivery platform (SDP) standard for providing multimedia applications in next generation networks (NGN). IMS defines an overlay service architecture that merges the paradigms and technologies of the Internet with the cellular and fixed telecommunication worlds. Its architecture enables the efficient provision of an open set of potentially highly integrated multimedia services, combining Web browsing, e-mail, instant messaging, presence, VoIP, video conferencing, application sharing, telephony, unified messaging, multimedia content delivery, etc. on top of possibly different network technologies. As such IMS enables various business models for providing seamless business and consumer multimedia applications. IMS platform also supports interworking with Internet and legacy networks.

In this article, we have provided background, motivation, standards, services, and architecture of IP multimedia subsystem (IMS), which is considered the next generation service platform toward all-IP networks. We have also tried to highlight the future trends and open issues in IMS.

KEY TERMS

Fixed-Mobile Convergence (FMC): FMC is the merger of fixed and mobile communication paradigms and IMS is considered as common platform for FMC granting convergence and compatibility between fixed/mobile networks, multimedia and converged services support, and providing key community service enablers such as group management, presence, IM/PoC and generic VoIP /MMoIP support.

IP Multimedia Subsystem (IMS): The IP multimedia subsystem (IMS) is standardised by 3GPP & 3GPP2 as next generation network (NGN) architecture to provide mobile and fixed multimedia services. It is based on VoIP, SIP, and IP protocols on the recommendation on 3rd Generation Partnership Project on top of GPRS/UMTS.

Next Generation Network (NGN): A next generation network (NGN) as defined by ITU-T is a packet-based network able to provide services including telecommunication services and able to make use of multiple broadband, QoS-enabled transport technologies and in which service-related functions are independent from underlying transport-related technologies. It offers unrestricted access by users to different service providers. It supports generalized mobility, which will allow consistent and ubiquitous provision of services to users.

Open System Architecture (OSA): The open system architecture (OSA) describes the service architecture for 3rd generation mobile telecommunications network or universal mobile telecommunication networks (UMTS). OSA Standards are being developed and published by as part of 3rd Generation Partnership Project (3GPP) and ETSI. The OSA APIs are developed by parlay group and is called OSA/Parlay service framework.

Service Delivery Platform (SDP): SDP is a foundation for the creation, deployment, provision, control, charging, and management of telecommunication services provided to the end users. The SDPs represent the programming interface enabling programming of the underlying network capabilities and therefore are primarily based in the usage of information technologies (ITs). SDP may apply to many technologies including VoIP, IPTV, HSD (high speed data), Mobile Telephony, Online Gaming, etc.

Third Generation Partnership (3GPP): The 3rd Generation Partnership Project (3GPP) is a collaboration agreement between mobile industries that was established in December 1998 to extend the GSM specifications toward Third Generation (3G) mobile system specifications within the scope of the ITU's IMT-2000 project. 3GPP specifications are generally known as the UMTS system.

Voice Over IP (VoIP): Voice over Internet protocol (VoIP) is the technology for sending voice calls on IP-based network instead of using conventional voice telecommunication networks. VoIP protocol is used to carry voice signals over IP networks.
